## Post Regulation Driver

The NCP4330 houses a dual MOSFET driver intended to be used as a companion chip in AC-DC or DC-DC multi-output post regulated power supplies. Being directly fed by the secondary AC signal, the device keeps power dissipation to the lowest while reducing the surrounding part count. Furthermore, the implementation of a N-channel MOSFET gives NCP4330-based applications a significant advantage in terms of efficiency.

### Features

- Undervoltage Lockout
- Thermal Shutdown for Overtemperature Protection
- PWM Operation Synchronized to the Converter Frequency
- High Gate Drive Capability
- Bootstrap for N-MOSFET High-Side Drive
- Over-Lap Management for Soft Switching
- High Efficiency Post-Regulation
- Ideal for Frequencies up to 400 kHz
- This is a Pb-Free Device

### Typical Applications

- ATX 3V3 Post-Regulation
- Offline SMPS with MAGAMP Post-Regulation
- Multi-Outputs DC-DC Converters

## DETAILED PIN DESCRIPTION(S)

Pin Number	Name	Function
1	HS_DRV	"HS_DRV" is the gate driver of the high-side MOSFET.
2	BST	"BST" is the bootstrap pin. A 0.1 $\mu$ F to 1.0 $\mu$ F ceramic capacitor should be connected between this pin and the node that is common to the coil and the two MOSFET. The "BST" voltage feeds the high-side driver ("HS_DRV").
3	RST	The "RST" pin resets the C_ramp voltage in order to synchronize the post-regulator free-wheeling sequence to the forward converter demagnetization phase.
4	C_ramp	The capacitor connected to the C_ramp pin enables to adjust the delay in turning on the high-side MOSFET (in conjunction with "I_ramp" current).
5	I_ramp	The "I_ramp" pin receives a current supplied by a regulation means. This current adjusts the delay after which the high-side MOSFET is turned on. By this way, it modulates the high-side MOSFET on time in order to regulate the output voltage.
6	V <sub>DD</sub>	"V <sub>DD</sub> " is the power supply input. A 0.1 $\mu$ F to 1.0 $\mu$ F ceramic capacitor should be connected from this pin to ground for decoupling.
7	LS_DRV	"LS_DRV" is the driver output of the low-side MOSFET gate.
8	GND	Ground.

## MAXIMUM RATINGS

Symbol	Rating	Value	Unit
BST	Bootstrap Input	-0.3, +40	V
RST	Reset Input	-0.3, +5.0	V
C_ramp	Timing Capacitor Node (Note 1)	-0.3, V <sub>rampHL</sub>	V
I_ramp	Regulation Current Input (Note 1)	-0.3, V <sub>cl</sub>	V
V <sub>DD</sub>	Supply Voltage	-0.3, +20	V
R <sub>θJA</sub>	Thermal Resistance	180	°C/W
T <sub>J</sub>	Operating Junction Temperature Range (Note 2)	-40, +125	°C
T <sub>Jmax</sub>	Maximum Junction Temperature	150	°C
T <sub>Smax</sub>	Storage Temperature Range	-65 to +150	°C
T <sub>Lmax</sub>	Lead Temperature (Soldering, 10 s)	300	°C

Maximum ratings are those values beyond which device damage can occur. Maximum ratings applied to the device are individual stress limit values (not normal operating conditions) and are not valid simultaneously. If these limits are exceeded, device functional operation is not implied, damage may occur and reliability may be affected.

1. V<sub>rampHL</sub> and V<sub>cl</sub> are the internal clamp levels of pins 4 and 5 respectively.
2. The maximum junction temperature should not be exceeded.

## ELECTRICAL CHARACTERISTICS (V<sub>DD</sub> = 10 V, V<sub>BST</sub> = 25 V, T<sub>J</sub> from -25°C to +125°C, unless otherwise specified.)

DETAILED OPERATING DESCRIPTION

**Introduction**

The NCP4330 is designed for forward, multiple output power supplies using synchronous rectification. One output is traditionally regulated thanks to a regulation arrangement that modulates the forward converter duty cycle. The other outputs are regulated by a dual MOSFET arrangement driven by the NCP4330. The high-side MOSFET turns on during one part of the forward converter on-time, while the low-side power switch is ON for the rest of the period (free wheeling).

The sequencing of the switching phases, includes over-laps that result in only one hard switching (high-side turn on). The three other transitions are soft for an optimum efficiency.

The synchronous rectification enables to keep a Continuous Conduction Mode (CCM) operation whatever the load is, as this technique allows to send back some energy towards the input (light load conditions). In Continuous Conduction Mode (CCM), the forward duty cycle is simply given by the following equation:

$$d_f = \frac{V_{out1}}{(n_s / n_p) * V_{in}}$$

- where: –  $d_f$  is the forward duty cycle,  
 –  $n_s/n_p$  is the transformer turn ratio ( $n_p$ : primary number of turns,  $n_s$ : secondary number of turns),  
 –  $V_{in}$  is the forward converter input voltage,  
 –  $V_{out1}$  is the main output voltage of the forward converter.

The post-regulated output voltages are given by the following equation:

$$V_{out_n} = d_n * \frac{n_s}{n_p} * V_{in},$$

where  $d_n$  is the duty cycle of the post-regulator  $n$ , with  $d_n < d_f$  since  $(n_s * V_{in} / n_p)$  is available only during the forward converter on-time.

Post-regulated output voltages are then necessarily lower than the main regulated one.

**Sequencing and Regulation Block**

The timing diagram of page 2 portrays the phases sequencing.

Typically, a regulation arrangement injects a current into pin 5, in order to adjust the high-side MOSFET duty cycle.

Pin 5 current is internally mirrored in order to charge the  $C_{ramp}$  capacitor. An internal comparator (1.0 V hysteresis) detects when the capacitor voltage exceeds the 2.5 V internal reference. At that moment, the low-side MOSFET turns off. 100 ns later (typically), the high-side MOSFET switches on and keeps on until (following the turn off of the forward converter power switch) a RESET signal is applied to pin 3. At that time, an internal switch grounds the  $C_{ramp}$  pin and abruptly discharges the  $C_{ramp}$  capacitor. As a consequence, the internal comparator turns low and forces the low-side MOSFET on. The high-side MOSFET turns off 100 ns later.

During the 100 ns during which both high and low side MOSFETs are on, the MOSFET Q1 of the application schematic is off and no energy can then be drawn from the converter transformer. Therefore, these 100 ns should not be considered as a part of the high-side MOSFET conduction time which can be computed as follows:

$$t_{on\_HS} = T_{sw} - t_{RST} - t_{LS,HS} - t_{charge}$$

- where: –  $T_{sw}$  is the forward switching period,  
 –  $t_{RST}$  is the  $C_{ramp}$  reset time during which the capacitor is kept grounded,  
 –  $t_{LS,HS}$  is the delay between the low-side turn off and the high-side switch on. During this time, 100 ns typically, the two drivers are in low state,  
 –  $t_{charge}$  is the time necessary to charge the  $C_{ramp}$  capacitor up to the 2.5 V reference voltage.

Given that:

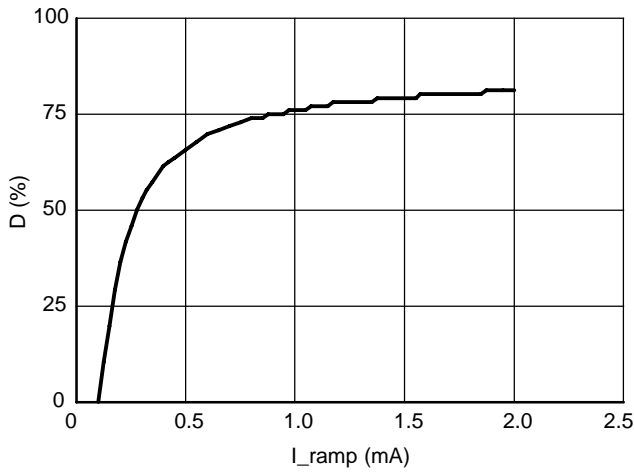

$$t_{charge} = \frac{C_{ramp} * V_{ref}}{I_{ramp}}$$

- where: –  $C_{ramp}$  is the capacitor connected to the  $C_{ramp}$  pin,  
 –  $I_{ramp}$  is the current injected into the  $I_{ramp}$  pin,  
 –  $V_{ref}$  is the 2.5 V reference voltage,

the following equation dictates the high-side MOSFET duty cycle:

$$d_{on\_HS} = 1 - \frac{t_{RST} + t_{LS,HS} + \frac{C_{ramp} * V_{ref}}{I_{ramp}}}{T_{sw}}$$

The following curve gives  $d_{on\_HS}$  versus the current  $I_{ramp}$  in the following conditions: 400 kHz switching frequency, 250 ns reset pulse duration, 100 ns switching delay (between LS and HS), 100 pF  $C_{ramp}$  capacitor.

**Figure 25. High-Side MOSFET Duty Cycle vs. I\_ramp**

**Conditions: Switching Frequency: 400 kHz, Reset Pulse Duration: 250 ns, Switching Delay (between LS and HS): 100 ns, Cramp = 100 pF.**

One can note that the duty cycle increases when the I\_ramp current increases. The duty cycle is zero if the I\_ramp current is below about 110  $\mu$ A.

The duty cycle is limited to about 81% mainly by the reset time and the 100 ns delay that all together represent 14% of the period. In a 100 kHz application, the relative impact of these times would be reduced and the maximum duty cycle would be higher (in the range of 92%).

In fact, the high-side on-times are useful only during the forward on-times. **Finally, if the duty cycle of the forward converter is less than 80%, one can consider that the useful post regulator duty cycle can vary between 0 and 100%.**

It can also be noted that the HS MOSFET can be turned on while the forward power switch is off, the forward free-wheeling MOSFET (Q2) is on and then no voltage is applied to the post-regulator. This is not an issue since the MOSFETs Q2 and Q3 derive the L2 coil current so that the

free wheeling operation continues (refer to application schematic).

However, such a situation should occur only during transient phases. Should this state occur too frequently, an excessive heating of the Q2 switch could be produced.

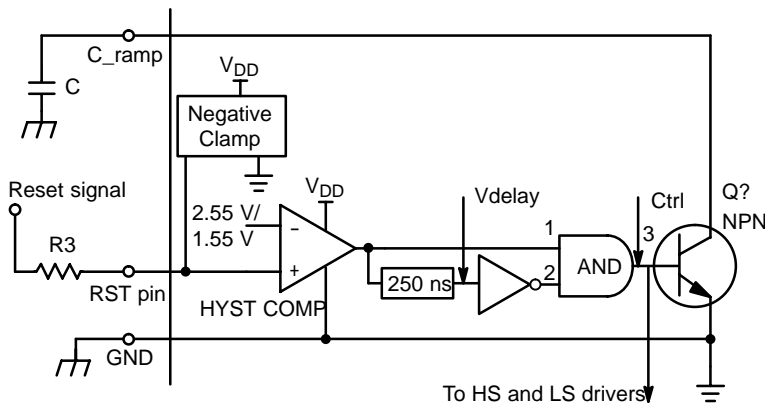

**Figure 26. HS MOSFET Duty Cycle vs. I\_ramp (zoom)**

**RESET Block**

The “reset” pin should receive the free-wheeling drive signal of the forward (refer to application schematic). When this voltage exceeds the reset block threshold (2.55 V typically), the C\_ramp capacitor is grounded by an internal switch for about 250 ns and the low-side MOSFET is turned on. The circuit is then initialized for a new cycle.

The voltage that is applied to the “reset” pin, may be negative during one part of the period. The NCP4330 incorporates a negative clamp system to avoid that too negative voltages on the pin may cause carriers injection within the die. The negative clamp acts to force a minimum voltage of about -0.3 V in conjunction with the external resistor R3. It features a current capability of about 2.0 mA.

**Figure 27. Reset Block**

**Low-Side Driver Stage**

The timing diagram of page 2 portrays the sequencing driven by the NCP4330.

The low-side drive is controlled by an internal comparator that compares the C<sub>ramp</sub> voltage to the internal reference 2.5 V (1.0 V hysteresis). When the C<sub>ramp</sub> exceeds the 2.5 V reference, the comparator turns high forcing the low-side MOSFET off. 100 ns later, the high-side MOSFET switches on.

When a reset signal is applied to the reset pin, the C<sub>ramp</sub> capacitor is grounded. As a consequence, the internal comparator turns low and forces the low-side MOSFET on. 100 ns later, the high-side MOSFET switches off.

The low-side drive is designed to drive on and off a 25 nC gate charge power MOSFET, in 25 ns typical.

**1. Low-Side MOSFET Turn On:**

In nominal operation, the body diode is already ON when the low-side MOSFET turns on. The energy Q<sub>g</sub> to be supplied is then approximately half the energy necessary if the drain source voltage was high.

The necessary current capability is then:

$$I_{S - on} = \frac{1}{2} * \frac{25 \text{ nC}}{25 \text{ ns}}, \text{ that is } 500 \text{ mA.}$$

**Figure 28. Low-Side MOSFET Turn ON**

**2. Low-Side MOSFET Turn Off:**

The high-side MOSFET turns on about 100 ns after the low-side one is switched off. During this time when both switches are off, the body diode of the low-side MOSFET derives the inductor current (in nominal load condition, when the coil current is positive, i.e., it flows toward the output). As a result, the LS MOSFET turns off while its drain-source voltage keeps around zero due to its body diode activation.

Again, the energy  $Q_g$  to be supplied is then approximately half its value if the drain source voltage was high.

The necessary current capability is then:

$$I_{ls-off} = \frac{1}{2} * \frac{25 \text{ nC}}{25 \text{ ns}}, \text{ that is } 500 \text{ mA.}$$

High  $dV/dt$  occur in the application. When the high-side MOSFET turns on, the drain-source voltage of the low-side MOSFET sharply increases, producing a huge current through the  $C_{rss}$  capacitor. This current may produce some parasitic turn on of the LS MOSFET if the driver impedance is not low enough to absorb this current without significant increase of the driver voltage. The driver current capability has then been increased to 750 mA so that it can effectively face a 30 V variation in 10 ns with a MOSFET exhibiting a 250 pF  $C_{rss}$ .

**Figure 29. Low-Side MOSFET Turn Off**

**High-Side Driver Stage**

The high-side turn on (turn off) is 100 ns delayed behind the low-side turn off (turn on).

The high-side drive is designed to drive on and off 12.5 nC gate charge power MOSFET, in 25 ns typical.

**1. High-Side Turn On:**

As portrayed by in figure 30, the high-side turn on is a “hard” switching (large dV/dt and dI/dt).

The necessary current capability is then:

$$I_{hs - on} = \frac{12.5 \text{ nC}}{25 \text{ ns}}, \text{ that is } 500 \text{ mA.}$$

**Figure 30. High-Side MOSFET Turn On**

**2. High-Side Turn Off:**

The high-side MOSFET turns in a very soft way (no current, no voltage). The turn off drive is in fact designed to face the high dV/dt that occurs when the MOSFET Q1

abruptly turns on. The current capability has been set to 750 mA so that a 30 V variation in 10 ns cannot parasitically switch on a high-side MOSFET exhibiting a 250 pF Crss.

**Figure 31. High-Side MOSFET Turn Off**

**3. Input Voltage Limitation:**

Traditional high-side drivers turn off the MOSFET they control, by forcing nearly 0 V between gate and source. The NCP4330 high-side stage is not referenced to the MOSFET source but to ground, and the HS MOSFET is forced off by grounding its gate. This technique that saves the pin that is traditionally connected to the MOSFET source, allows a robust turn off of the power switch. In effect, the low-side MOSFET that is ON when the high-side is off, forces the High-side MOSFET source to approximately 0 V.

However the high-side MOSFET turn on is preceded by a 100 ns phase during which both the low-side and high-side power switches are off. During this 100 ns phase, the drain source voltage of the low-side MOSFET may get high, given that in light load operation, the L2 coil current may get negative and flow from the load toward the input through the HS MOSFET body diode. In this case, the gate source voltage of the high-side MOSFET becomes negative and substantially equal to the input voltage amplitude of the post-regulator in absolute value.

*Therefore, the maximum value of the pulsed input voltage should be chosen lower than the maximum source-gate voltage the HS MOSFET can sustain. Traditional MOSFET Vgs maximum ratings are generally +/-20 V. Therefore, with this kind of MOSFETs, the input voltage must keep below 20 V (possible spikes being included).*

**Undervoltage Lockout**

An undervoltage lockout comparator is incorporated to guarantee that the device is fully functional before enabling the output stages. The NCP4330 starts to operate when the power supply VDD exceeds 5.8 V. A 600 mV hysteresis avoids that some noise on the VDD might produce some erratic turns on and off of the device. When the NCP4330 detects an undervoltage lockout condition, it keeps both the high-side and low-side drivers in low state.

The undervoltage lockout has a 4.9 V minimum threshold (falling). As a consequence, around 3.4 V are available on the driver outputs to force on the MOSFET. Such a level allows to properly drive most MOSFETs.

## NCP4330

If the input voltage may exceed the maximum source–gate voltage the HS MOSFET can sustain, an intermediary stage should be inserted between the NCP4330 and the HS MOSFET. Figure 33 presents a solution consisting of a

diode, a PNP and a resistor (in the range of 500  $\Omega$ ). The HS MOSFET is normally turned on through the diode while the PNP Q2 enables to drive the MOSFET between gate and source at turn off.
