Compiled Gate Level SRAMs

Atmel offers a variety of compiled gate level SRAMs for the ATL60 series of gate arrays. These static asynchronous SRAMs utilize the personalization layers and occupy standard gate array sites. The SRAMs come in either dual port or single port architectures.

The dual port SRAMs have two sets of address inputs, a read address (RD_ADDR) and a write address (WR_ADDR). The output of the SRAM is the word which is pointed to by the read address. When the WE (Write Enable) input goes low, the word on the DIN bus is written to the address specified by the write address.

The single port SRAMs have one set of address inputs (ADDR) which control both write and read

operations. The output of the SRAM is always the word which is pointed to by the address inputs. When the WRITE input goes low, the word on the DIN bus is written to the address specified by the address input.

Both single port and dual port SRAMs have enables (OE) on their outputs. The outputs stay high while the output enable signal is high.

The SRAMs can be compiled in depths ranging from 2 words to 32 words. The following tables give size information for some common SRAM sizes. Contact Atmel for the exact size of any SRAM not listed.

Common Single Port SRAM Sizes

		SRAM Width (bits)

Below are symbols for 4 x 4 single and dual port SRAMs (PRAM4X4SUB32 and PRAM4X4SUB32). Note that the unused address inputs must be tied to VSS or the SRAM will not function properly (i.e. ADDR4 is tied low for SRAMs smaller than 18 words, ADDR3 for SRAMs smaller than 10 words,

ADDR2 for SRAMs smaller than 6 words, and ADDR1 for a 2 word SRAM). Unused RD_ADDR and WR_ADDR inputs need to be tied to VSS for dual port SRAMs. The SRAMs can be multiplexed to create a deeper SRAM.

PRAM48X4

The following pages contain the SRAM write and read timing which was gathered from running Spice simulations. The write timing was determined by measuring the propagation delay from the WRITE, ADDR, and DIN pins to the memory latch bit on a large (32x36) and small (2x2) SRAM. The times given were measured from the input pins to when the actual data in memory changed. This was done by initializing the SRAM to a specific state such that if only the input pin under analysis changed, the memory bit would be changed. The delays were measured for the memory bit rising and falling. The

longest path to a memory latch bit on the large SRAM represents the maximum delay and the shortest path to a memory latch bit on the small SRAM represents the minimum delay. The setup and hold timing were derived from these delays. The equations used are given with the specifications. The read timing was determined by measuring the propagation delay through the SRAMs. These Spice simulations were run with best, typical, and worst temperature and process conditions. Four unit loads were applied to the SRAM outputs for the Spice simulations.
