## MC44605

## High Safety, Latched Mode, GreenLine ${ }^{\text {w }}$ PWM Controller for (Multi) Synchronized Applications

The MC44605 is a high performance current mode controller that is specifically designed for off-line converters. This circuit has several distinguishing features that make it particularly suitable for multisynchronized monitor applications.

The MC44605 synchronization arrangement enables operation from 16 kHz up to 130 kHz . This product was optimized to operate with universal mains voltage, i.e., from 80 V to 280 V , and its high current totem pole output makes it ideally suited for driving a power MOSFET.

The MC44605 protections enable a well-controlled and safe power management. Four major faults while detected, activate the analogic counter of a disabling block designed to perform a latched circuit output inhibition.

## Features

- Pb -Free Package is Available*

## Current Mode Controller

- Current Mode Operation up to 250 kHz Output Switching Frequency
- Inherent Feed Forward Compensation
- Latching PWM for Cycle-by-Cycle Current Limiting
- Oscillator with Precise Frequency Control
- Externally Programmable Reference Current
- Secondary or Primary Sensing (Availability of Error Amplifier Output)
- Synchronization Facility
- High Current Totem Pole Output
- $\mathrm{V}_{\mathrm{cc}}$ Undervoltage Lockout with Hysteresis
- Low Output dV/dT for Low EMI Radiations
- Low Startup and Operating Current

## Safety/Protection Features

- Soft-Start Feature
- Demagnetization (Zero Current Detection) Protection
- Overvoltage Protection Facility against Open Loop
- EHT Overvoltage Protection (E.H.T.OVP): Detection of too High Synchronization Pulses
- Winding Short Circuit Detection (W.S.C.D.)
- Limitation of the Maximum Input Power (M.P.L.): Calculation of Input Power for Overload Protection
- Overheating Detection (O.H.D.): to Prevent the Power Switch from an Excessive Heating

## Latched Disabling Mode

- When one of the following faults is detected: EHT overvoltage, Winding Short Circuit (WSCD), a too high input power (M.P.L.), power switch overheating (O.H.D.), an analogic counter is activated
- If the counter is activated for a time that is long enough, the circuit gets definitively disabled. The latch can only be reset by making decrease the $\mathrm{V}_{\mathrm{cc}}$ down to about 3.0 V , i.e., practically by unplugging or turning off the SMPS.

MPL \& OHD SECTION

| MPL Parameter (Note 10) |  | $\Gamma_{M P L}$ | 0.185 | 0.240 | 0.295 |
| :--- | :---: | :---: | :---: | :---: | :---: |
| MPL Comparator Threshold (Note 11) |  | $V^{-1}$ |  |  |  |
| OHD Parameter (Note 12) |  | $\Gamma_{\text {OHD }}$ | 1.15 | 1.50 | 1.85 |
| OHD Comparator Threshold (Note 13) |  | $V_{\text {OHD-th }}$ | 2.4 | 2.5 | 2.6 |

5. Adjust $\mathrm{V}_{\mathrm{Cc}}$ above the startup threshold before setting to 12 V . Low duty cycle pulse techniques are used during test to maintain junction temperature as close to ambient as possible.
6. This function can be inhibited by connecting pin 8 to GND. In this case, there is a minimum off-time equal to $T_{\text {DEM-GND. }}$
7. The MC44605 can be shut down by connecting soft-start pin (pin 11) to GND.
8. The circuit is shutdown if the soft-start pin voltage is lower than this level.
9. This function can be inhibited by connecting pin 9 to GND. In this case, the synchronization block is inhibited too and the MC44605 works in free mode.
10. This parameter is defined in the MPL §. This parameter is obtained by measuring the MPL pin average current and dividing this result by the corresponding squared $V_{C S}$, the measured frequency value and the $\mathrm{C}_{\mathrm{T}}$ value deducted from the measured frequency value.
Measurement conditions: $\mathrm{V}_{\text {Feedback(pin 14) }}=2.3 \mathrm{~V}, \mathrm{~V}_{\text {soft-start(pin 11) }}=0.5 \mathrm{~V}$ and pins 7,8 , and 9 connected to GND (the working frequency is typically equal to $18 \mathrm{kHz}-\mathrm{R}_{\text {ref }}=10 \mathrm{k} \Omega \pm 1 \%, \mathrm{C}_{\mathrm{T}}=2.2 \mathrm{nF}$ ).
11. The MPL comparator output is Dis MPL.
12. This parameter is defined in the OHD $\S$. This parameter is obtained by measuring the OHD pin average current and dividing this result by the corresponding squared $\mathrm{V}_{\mathrm{CS}}$ value and multiplying it by the $\mathrm{R}_{\text {ref }}$ value.
Measurement conditions: $\mathrm{V}_{\text {Feedback(pin 14) }}=2.3 \mathrm{~V}, \mathrm{~V}_{\text {soft-start(pin 11) }}=0.5 \mathrm{~V}$ and pins 7, 8 , and 9 connected to GND (the working frequency is typically equal to $18 \mathrm{kHz}-\mathrm{R}_{\text {ref }}=10 \mathrm{k} \Omega \pm 1 \%, \mathrm{C}_{\mathrm{T}}=2.2 \mathrm{nF}$ ).
13. The OHD comparator output is Dis $\mathrm{OHD}^{\text {OH. }}$

TOTAL DEVICE

14. Adjust $\mathrm{V}_{\mathrm{CC}}$ above the startup threshold before setting to 12 V . Low duty cycle pulse techniques are used during test to maintain junction temperature as close to ambient as possible.
15. Once a fault detection activated it, the Disabling Block Latch gets reset when the $\mathrm{V}_{\mathrm{CC}}$ becomes lower than this threshold.
16. Refer to Note 14.
17. This consumption is measured while the circuit is inhibited by the Definitive Latch.

| Pin | Name |  |
| :---: | :---: | :--- |
| 1 | $V_{\text {CC }}$ | This pin is the positive supply of the IC. |
| 2 | $V_{C}$ | The output high state, $V_{\text {OH }}$, is set by the voltage applied to this pin. With a separate <br> connection to the power source, it gives the possibility to set by means of an external <br> resistor the output source current at a different value than the sink current. |
| 3 | Output | The output current capability is suited for driving a power MOSFET. |

## MC44605

## Summary of the Main Design Equations

The following table consists of equations enabling to dimension a multisynchronized SMPS operating in discontinuous mode.

| $\text { Pin }_{\max }=\frac{\text { Pout }_{\max }}{\eta}$ | Pout $_{\text {max }}$ is the maximum power the load may draw in normal working. <br> The maximum input power $\mathrm{Pin}_{\text {max }}$ is easily deducted by dividing Pout $_{\text {max }}$ by the efficiency $(\eta)$. In this kind of application, the efficiency is generally taken equal to 80\%. |
| :---: | :---: |
| $L p_{\max }=\frac{\left[\frac{\sqrt{2} \cdot \mathrm{Vac}_{\text {min }} \times \mathrm{NVo}}{\sqrt{2} \cdot \mathrm{Vac}_{\text {min }}+\mathrm{NVo}}\right]^{2}}{2 \times \mathrm{Pin}_{\max } \times \mathrm{fsync}_{\text {max }}}$ | The inductor value Lp must be chosen lower than $\mathrm{Lp} \mathrm{max}_{\text {max }}$ or ideally equal to this value (to optimize the application design-in). <br> In effect, if Lp was higher than $\mathrm{Lp}_{\text {max }}$, a synchronized and discontinuous working could not be guaranteed (in some cases, the demagnetization phase would not be finished while a new conduction phase should start to follow the synchronization). |
| $\mathrm{Ipk} \mathrm{max}_{\text {max }}=\sqrt{\frac{2 \times \mathrm{Pin}_{\text {max }}}{\mathrm{L} \mathrm{\times} \mathrm{fsync}}{ }_{\text {min }}}$ | $\mathrm{Ipk}_{\text {max }}$ is the maximum inductor peak current. This current is obtained when the power to transfer is maximum at the minimum synchronization frequency ( 60 W output, 30 kHz in the proposed application). |
| $\mathrm{d}_{\text {max }}=\frac{\sqrt{\mathrm{Pin}_{\text {max }} \times \mathrm{Lp} \times \mathrm{fsync}_{\text {max }}}}{\mathrm{Vac}_{\text {min }}}$ | $d_{\text {max }}$ is the maximum duty cycle. The duty cycle is maximum at the lowest input voltage when the power demand is maximum while the synchronization frequency also is maximum. |
| $\mathrm{Pon}_{\text {max }}=\frac{1}{3} \times \mathrm{Rds}_{\text {on }} \times \mathrm{lpk}_{\text {max }}{ }^{2} \times \mathrm{d}_{\text {max }}$ | $\mathrm{Pon}_{\text {max }}$ is the maximum MOSFET on-time losses that are proportional to $\mathrm{Ipk}_{\text {max }}$, $\mathrm{d}_{\text {max }}$ and Rds on (on-time MOSFET resistor). <br> This conduction losses estimation enables to dimension the power MOSFET. |
| $\left(\mathrm{V}_{\mathrm{DS}}\right) \max =\left(\sqrt{2} \times \mathrm{Vac}_{\text {max }}\right)+(\mathrm{N} \times$ Vout $)$ | ( $V_{D S}$ )max is the maximum voltage the power switch must be able to face. In fact, this calculation does not take into account the turnings off spikes. So, it is necessary to take a margin of at least about 50 V . |
| $\left(\mathrm{V}_{\mathrm{D}}\right) \max =\left(\sqrt{2} \times \frac{\mathrm{Vac}_{\text {max }}}{\mathrm{N}}\right)+$ Vout | $\left(V_{D}\right)$ max is the maximum voltage the high voltage secondary diode must be able to face. Because of the turning off spikes, a margin must also be taken. |

| $A_{L}=\frac{L_{P}}{\left(N \times n_{\text {Vout }}\right)^{2}}$ | $\left(A_{L}\right)$ is the ferrite constant that links the primary inductor value to the squared number of primary turns: $L p=A_{L} \times n_{p}{ }^{2}$. |

## Error Amplifier

A fully compensated Error Amplifier with access to the inverting input and output is provided. It features a typical DC voltage gain of 70 dB . The non inverting input is internally biased at 2.5 V and is not pinned out. The converter output voltage is typically divided down and monitored by the inverting input. The maximum input bias current with the inverting input at 2.5 V is $-2.0 \mu \mathrm{~A}$. This can cause an output voltage error that is equal to the product of the input bias current and the equivalent input divider source resistance.

Figure 1. Error Amplifier Compensation

The Error Amp Output (Pin 13) is provided for external loop compensation. The output voltage is offset by two diodes drops ( $\approx 1.4 \mathrm{~V}$ ) and divided by three before it connects to the inverting input of the Current Sense Comparator. This guarantees that no drive pulses appear at the Source Output (Pin 3) when Pin 13 is at its lowest state ( $\mathrm{V}_{\mathrm{OL}}$ ). This occurs when the power supply is operating and the load is removed, or at the beginning of a soft-start interval. The Error Amp minimum feedback resistance is limited by the amplifier's minimum source current $(0.2 \mathrm{~mA})$ and the required output voltage $\left(\mathrm{V}_{\mathrm{OH}}\right)$ to reach the current sense comparator's 1.0 V clamp level:

$$
\mathrm{R} 1(\mathrm{~min})=\frac{(3 \times 1 \mathrm{~V})+1.4 \mathrm{~V}}{0.2 \mathrm{~mA}}=22 \mathrm{k} \Omega
$$

## Current Sense Comparator and PWM Latch

The MC44605 operates as a current mode controller. The circuit uses a current sense comparator to compare the inductor current to the threshold level established by the Error Amplifier output (Pin 13). When the current reaches the threshold, the current sense comparator terminates the output switch conduction that has been initiated by the oscillator, by resetting the PWM Latch. Thus the error signal controls the peak inductor current on a cycle-by-cycle basis. This configuration ensures that only one single pulse appears at the Source Output during the appropriate oscillator cycle.

Figure 2. Output Totem Pole

The inductor current is converted to a voltage by inserting the ground referenced sense resistor $\mathrm{R}_{\mathrm{S}}$ in series with the power switch Q1.

This voltage is monitored by the Current Sense Input (Pin 7) and compared to a level derived from the Error Amp output. The peak inductor current under normal operating conditions is controlled by the voltage at Pin 13 where:

$$
\mathrm{I}_{\mathrm{pk}} \approx \frac{\mathrm{~V}_{(\mathrm{pin} 13)}-1.4 \mathrm{~V}}{3 \times \mathrm{R}_{\mathrm{S}}}
$$

The Current Sense Comparator threshold is internally clamped to 1.0 V . Therefore the maximum peak switch current is:

$$
I_{\mathrm{pk}(\max )}=\frac{1 \mathrm{~V}}{\mathrm{R}_{\mathrm{S}}}
$$

## Undervoltage Lockout Section

As depicted in Figure 3, an undervoltage lockout has been incorporated to guarantee that the IC is fully functional before allowing the system working.
In effect, the $\mathrm{V}_{\mathrm{CC}}$ is connected to the non inverting input of a comparator that has an upper threshold equal to 14.5 V (typical $\mathrm{V}_{\text {stup-th }}$ ) and a lower one equal to 7.5 V (typical $\mathrm{V}_{\text {disable 2 }}$ ). This hysteresis comparator enables or disables the reference block that generates the voltage and current sources required by the system.
This block particularly, produces $\mathrm{V}_{\text {ref }}$ (pin 16 voltage) and $\mathrm{I}_{\text {ref }}$ that is determined by the resistor $\mathrm{R}_{\text {ref }}$ connected between pin 16 and the ground:

$$
I_{\text {ref }}=\frac{V_{\text {ref }}}{R_{\text {ref }}} \text { where } V_{\text {ref }}=2.5 \mathrm{~V} \text { (typically) }
$$

Figure 3. $\mathrm{V}_{\mathrm{Cc}}$ Management
In addition to this, $\mathrm{V}_{\mathrm{CC}}$ is compared to a second threshold level that is nearly equal to $9.0 \mathrm{~V}\left(\mathrm{~V}_{\text {disable1 }}\right)$ so that a signal UVLO1 is generated to reset the soft-start block and so, to disable the output stage (refer to the Soft-Start §) as soon as $\mathrm{V}_{\mathrm{CC}}$ becomes lower than $\mathrm{V}_{\text {disable 1 }}$. In this way, the circuit is reset and made ready for a next startup, before the reference block is disabled (refer to Figure 3). Thus, finally the upper limit for the minimum normal operating voltage
is 9.4 V (maximum value of $\mathrm{V}_{\text {disable 1 }}$ ) and so the minimum hysteresis is 4.2 V . $\left[\left(\mathrm{V}_{\text {stup-th }}\right)_{\min }=13.6 \mathrm{~V}\right]$.

The large hysteresis and the low startup current of the MC44605 make it ideally suited for off-line converter applications where efficient bootstrap startup techniques are required.

## Soft-Start Control Section

The $\mathrm{V}_{\mathrm{cs}}$ value is clamped down to the pin 11 voltage.
So, if a capacitor is connected to this pin, its voltage increases slowly at the startup (the capacitor is charged by an internal current source $0.4 \mathrm{I}_{\text {ref }}$ ). So, $\mathrm{V}_{\mathrm{cs}}$ is limited during the startup and then a soft-start is performed.

This pin can be used to inhibit the circuit by applying a voltage that is lower than $\mathrm{V}_{\text {SSinhi }}$ (refer to page 4). Particularly, the MC44605 can be shutdown by connecting the soft-start pin to ground.

As soon as $\mathrm{V}_{\text {dis } 1}$ is detected (that is $\mathrm{V}_{\mathrm{cc}}$ lower than $\mathrm{V}_{\text {disable1 }}$ ), a signal UVLO1 is generated until the $\mathrm{V}_{\mathrm{cc}}$ falls down to $\mathrm{V}_{\mathrm{dis} 2}$ (refer to the undervoltage lockout section §). During the delay between the disable1 and the disable2, using a transistor controlled by UVLO1, the pin 11 voltage is made equal to zero in order to make the soft-start arrangement ready to work for the next re-start.

Figure 4. Soft-Start

## Oscillator Section (Figures 5 \& 5b)

The oscillator and synchronization behavior is represented in Figure 5b.

The MC44605 oscillator achieves four functions:

- it fixes the free mode frequency
- it takes into account the synchronization signal
- it does not allow a new power switch conduction if the flyback is not in a dead-time state when the circuit works in demagnetization mode (pin 8 connected)
- it builds the Sf pulse required by the MPL block

During the operating mode, the oscillator sawtooth can vary between a valley value ( 1.6 V typically) and a peak one (3.6 V typically) and presents three distinct phases:

- the $\mathrm{C}_{\mathrm{T}}$ charge
- the $\mathrm{C}_{\mathrm{T}}$ discharge
- the phase during which the oscillator voltage is maintained equal to its valley value. This happens at the end of a discharge cycle when the synchronization or demagnetization condition does not allow a new $\mathrm{C}_{\mathrm{T}}$ charge phase. During this sequence, $\mathrm{I}_{\text {REGUL }}$ compensates the charge current $\mathrm{I}_{\text {charge }}$.
The oscillator has two working modes:
- a free one when there is no synchronization
- a synchronized one.

In the free working, the oscillator grows up from its valley value to its peak one for the charge phase and when once the peak value is reached, a discharge sequence makes the $\mathrm{C}_{\mathrm{T}}$ voltage decrease down to its valley value. When the decrease phase is finished, a new charge cycle occurs if the demagnetization condition is achieved $\left(\mathrm{V}_{\mathrm{DT}}\right.$ high). Otherwise there is a REGUL phase until $\mathrm{V}_{\text {DT }}$ gets high.
In the synchronized mode, the charge cycle is only allowed when the synchronization signal gets high while a dead time has been detected ( $\mathrm{V}_{\mathrm{DT}}$ high). This charge phase is stopped when the synchronization signal has got low and when the oscillator voltage is higher than $\mathrm{V}_{\mathrm{in}}$, the intermediary voltage level used to generate the calibrated pulse Sf by comparing the $\mathrm{C}_{\mathrm{T}}$ voltage to this threshold. So , when these two conditions are performed, a discharge sequence is set until the oscillator voltage is equal to its valley value. Then, the $\mathrm{C}_{\mathrm{T}}$ voltage is maintained constant thanks to the "REGUL" arrangement until the next synchronization pulse.
In both cases, during the charge phase, a signal $\mathrm{V}_{\mathrm{S}}$ is generated. When Sf becomes high. $\mathrm{V}_{\mathrm{S}}$ gets high and remains in this state until the PWN latch is set of Sf is low. Then, $\mathrm{V}_{\mathrm{S}}$ keeps low until the next Sf high level. This oscillator behavior is obtained using the process described in Figure 5b.

Figure 5b. Oscillator Behavior

In effect, the output of the latch L 1 is:

- high during the oscillator capacitor charge and during the REGUL phase
- low for the oscillator capacitor discharge

Now, the latch L2 is set when the L1 output is high and the synchronization condition is performed (that is: sync $=1-$ free mode or synchro signal high state) and during the dead-time ( $\mathrm{V}_{\mathrm{DT}}$ high). So, this latch is set for the $\mathrm{C}_{\mathrm{T}}$ charge.

On the other hand, this latch is reset by the signal used to reset L1. Consequently, it is reset at the end of the charge phase.

So, in any case, $\mathrm{Q}_{\mathrm{L} 2}$ is:

- high during the $\mathrm{C}_{\mathrm{T}}$ charge cycle
- low in the other cases

Thus, this latch enables to obtain a signal that is high for the charge phase and low in the other cases, whatever the mode (synchronized or free) and whatever the synchronization pulses width (higher than the delay necessary for the oscillator to reach its intermediary value or lower than this delay) in the synchronized mode.

That is why:

- the discharge current source must be connected to the oscillator capacitor when $\mathrm{Q}_{\mathrm{L} 1}$ is low. The condition $\left(\mathrm{C}_{\mathrm{T}}\right.$ voltage higher than the valley value) is added to stop the discharge phase as soon as the oscillator voltage is detected as lower than the valley value (without any delay due to the L1 latch propagation time).
- the REGUL current source must be connected when:
- QL1 is high (charge or REGUL phase)
- $\mathrm{Q}_{\mathrm{L} 2}$ is low (the oscillator is not in a charge phase)

On the other hand, the oscillator charge is stopped when:

- the oscillator voltage reaches the peak value in the free mode
- the oscillator voltage is higher than the intermediary value $\left(\mathrm{V}_{\mathrm{int}}\right)$ and the synchronization signal is negative, in the synchronized mode.
Consequently, in any case, $\mathrm{Q}_{\mathrm{L} 2}$ that is high during the oscillator charge phase, is high for the delay during which the oscillator voltage grows from the valley value up to the intermediary one. That is why the signal Sf (refer to the MPL block) that must be high when the oscillator voltage is between the valley value and the intermediary one during the charge phase ( $\mathrm{Q}_{\mathrm{L} 2}$ high), is obtained using an AND gate with the following inputs:
- $\mathrm{Q}_{\mathrm{L} 2}\left(\mathrm{Q}_{\mathrm{L} 2}\right.$ high $\Leftrightarrow$ charge phase)
- Coscint (Coscint high $\Leftrightarrow$ ) the $\mathrm{C}_{\mathrm{T}}$ voltage is lower than the intermediary value).
So, using the output of this AND gate, Sf is obtained.
This signal Sf is connected to a logic block consisting of two AND gates and an OR one. This block aims at supplying a signal VS that:
- gets high as soon as Sf becomes high if the PWM latch output is low
- gets low as soon as the PWM latch is set and then remains low until the next cycle.

Figure 5. Oscillator

## Synchronization Section (Note 1)

The synchronization block consists of a protection arrangement similar to the demagnetization block one (a diode + a negative active clamping system (Note 2)). In addition to this, a high value resistor ( $\mathrm{R}-$ about $50 \mathrm{k} \Omega$ ) is incorporated as the pin 9 input is also used by the EHTOVP section.

The signal obtained at the output of this protection arrangement, is compared to a negative threshold ( -200 mV , typically) so that when the synchronization pulse applied to the pin 9 (through a resistor or a resistors divider to adapt this input to the EHTOVP function), is higher than this threshold, the system considers that the synchronization condition is performed (free mode or synchronization signal high level).
Note 1. The synchronization can be inhibited by connecting the pin 9 to the ground. By this means, a free mode is obtained.
Note 2. This negative active clamping system works even if the circuit is off. This feature is really useful as synchronization pulses may be applied while the product is off.

Figure 6. Synchronization

## Demagnetization Section

This block is incorporated to detect the complete core demagnetization in order to prevent the power MOSFET from switching on if the converter is not in a dead time phase. That is why this block inhibits any oscillator re-start as long as the inductor current is not finished (from the beginning of the on-time to the end of the demagnetization phase).

In a fly-back, a good means to detect the demagnetization phase consists in using the $\mathrm{V}_{\mathrm{CC}}$ winding voltage. In effect, this voltage is:

- negative during the on-time,
- positive during the off-time,
- equal to zero for the dead-time with generally a ringing (refer to Figure 7).

Figure 7. Demagnetization Detection

That is why, the MC44605 demagnetization detection consists of a comparator that compares the $\mathrm{V}_{\mathrm{CC}}$ winding voltage to a reference that is typically equal to 65 mV .

A diode D is incorporated to clamp the positive applied voltages while an active clamping system limit the negative voltages to typically -0.33 V . This negative clamp level is high enough to avoid the substrate diode switching on.

A latch system is incorporated to keep the demagnetization block output level low as soon as a voltage lower than 65 mV is detected and as long as a new restart is produced (high level on the output (refer to Figure 8). This process avoids that any ringing on the signal used on the pin 8, disrupts the demagnetization detection (refer to Figure 7). Finally, this method results in a very accurate demagnetization phase detection, and the signal $\mathrm{V}_{\mathrm{DT}}$ drawn from this block is high only for the dead time. Therefore, an oscillator re-start and so, a new power switch conduction is only allowed during the dead-time.

For a higher safety, the $\mathrm{V}_{\text {demagout }}$ output of the demagnetization block is also directly connected to the output, to disable it during the demagnetization phase (refer to the block diagram).

The demagnetization detection can be inhibited by connecting pin 8 to the ground but in this case, a timer (about $3 \mu \mathrm{~s}$ ) that is incorporated to set the latch when it can not be set by $\mathrm{V}_{\text {demagout }}$, results in a minimum off-time (refer to Figure 8).

Figure 8. Demagnetization Block

## Overvoltage Protection Section

The overvoltage arrangement compares a portion $\mathrm{V}_{\mathrm{cc}}$ to $\mathrm{V}_{\text {ref }}(2.5 \mathrm{~V})$ (refer to Figure 9). In fact, this threshold corresponds to a $\mathrm{V}_{\mathrm{CC}}$ equal to to 17 V . When the $\mathrm{V}_{\mathrm{cc}}$ is higher than this level, the output is latched off until a new circuit re-start.

Figure 9. Overvoltage Protection
A delay ( $2 \mu \mathrm{~s}$ ) is incorporated in order to avoid any activation due to interferences by only taking into account the overvoltages that last at least $2 \mu \mathrm{~s}$.

The $\mathrm{V}_{\mathrm{CC}}$ is connected when once the circuit has started-up in order to limit the circuit startup consumption ( T is switched on when once $\mathrm{V}_{\text {ref }}$ has been generated).

The overvoltage section is enabled $5 \mu$ s after the regulator has started to allow the reference $\mathrm{V}_{\text {ref }}$ to stabilize.

## E.H.T. Overvoltage Protection Section

This block uses the synchronization input as this section is incorporated to detect too high synchronization pulses and then to activate the device definitive latch in this case.

Figure 10. E.H.T. OVP

This block consists of a high impedance resistors bridge ( R is nearly equal to $50 \mathrm{k} \Omega$ - refer to Figure 10) so that the EHTovp threshold is 7.5 V . So, using an external resistors bridge ( $\mathrm{r} 1, \mathrm{r} 2 \ll \mathrm{R}$ ), the synchronization pulse level above which the working must be considered as wrong, can be adjusted.

For instance, if this threshold value is required to be equal to $30 \mathrm{~V}, \mathrm{~V}_{\text {pin9 }}$ must be equal to 7.5 V when the synchronization pulse value is 30 V .

So, in this case:

$$
30 \times \frac{\mathrm{r} 2}{\mathrm{r} 1+\mathrm{r} 2}=7.5
$$

Then, the ratio (r1/r2) can be deducted:

$$
\frac{\mathrm{r} 1}{\mathrm{r} 2}=3
$$

So, as r1 and r2 must be negligible in relation to R (about $50 \mathrm{k} \Omega$ ), the couple of resistors can be chosen as follows:

$$
\mathrm{r} 1=3 \mathrm{k} \Omega
$$

and:

$$
\mathrm{r} 2=1 \mathrm{k} \Omega
$$

## Winding Short Circuit Detection Section (WSCD)

The MC44605 being designed to control a Fly-Back SMPS, this block is incorporated to detect a short circuit on a transformer winding or on an output diode (refer to Figure 11).

Figure 11. Winding Short Circuit Fault

In the case of a Winding Short Circuit, the primary inductor $L_{p}$ is short circuited and then the current increase is only controlled by the leakage inductor $\mathrm{L}_{\text {leak }}$.

In current mode, the power switch conduction is stopped when the inductor current is detected as high enough, by the controller. In fact, when the current sense resistor $\left(\mathrm{R}_{\mathrm{s}}\right)$ voltage gets equal to $\mathrm{V}_{\mathrm{cs}}$, the current sense comparator switches to reset the output.

Now, the circuit has a propagation delay and the power switch needs some time to turn off. Consequently, there is a delay $\Delta t$ between the moment at which the $\mathrm{R}_{\mathrm{s}}$ voltage gets equal to $\mathrm{V}_{\mathrm{cs}}$ and the actual current increase stop. So, this results in an overcurrent (refer to Figure 12).

Figure 12. Overcurrent in a WSCD Case

Now, in normal working, this overcurrent $\Delta \mathrm{Ipk}$ is equal to:

$$
\Delta \mathrm{lpk}=\frac{\operatorname{Vin} \times \delta \mathrm{t}}{\mathrm{~L}_{\mathrm{P}}}
$$

where: $\mathrm{V}_{\mathrm{in}}$ is the input voltage (rectified a.c. line)
While in a WSCD case:

$$
(\Delta \mathrm{lpk})_{\mathrm{WSCD}}=\frac{\mathrm{Vin} \times \delta \mathrm{t}}{\mathrm{~L}_{\text {Leak }}}
$$

Consequently, as the leakage inductor value is generally much lower than the primary one (less than $5 \%$ generally), the overcurrent is much higher in the WSCD case. That is why this fault can be detected by detecting the high overcurrents.

So, the WSCD block consists of comparing the sensed current to a reference equal to: $\left(\mathrm{V}_{\mathrm{cs}}+\mathrm{V}_{\text {shift }}\right)$, where $\mathrm{V}_{\text {shift }}$ is a voltage proportional to the current injected in the pin 15 (refer to Figure 13).

Figure 13. WSCD

Now, as the overcurrent level depends on the input voltage $V_{\text {in }}$, it is preferable to use a $V_{\text {shift }}$ proportional to this input voltage instead of a constant $\mathrm{V}_{\text {shift }}$. So, the WSCD pin must be connected to $\mathrm{V}_{\text {in }}$ through a resistor that fixes $\mathrm{V}_{\text {shift }}$ by adjusting the current injected in this pin 15.

Finally, when there is a winding short circuit, an overcurrent is detected by the WSCD comparator. The output of this comparator, $\mathrm{V}_{\mathrm{WSCD}}$, is connected to the disabling block (refer to the disabling block §).

## Maximum Power Limitation Section (MPL)

The MPL block is designed to calculate this input power using the following equation:

$$
\text { Pin }=\frac{1}{2} \times L_{P} \times \mathrm{lpk}^{2} \times f
$$

where: Lp is the inductor value
Ipk is the inductor peak current
f is the switching frequency
As $\mathrm{V}_{\mathrm{cs}}$ is proportional to the inductor peak current $\left(V_{c s}=R_{s} \times\right.$ Ipk $)$, the squared Ipk value is estimated by building a current source proportional to $\mathrm{V}_{\mathrm{cs}}{ }^{2}$. This current is chopped by a calibrated pulse Sf , generated at each new oscillator cycle (refer to Figure 14).

Finally, using an external resistor and capacitor network ( $\mathrm{R}_{\mathrm{MPL}}, \mathrm{C}_{\mathrm{MPL}}$ ) on the MPL pin, a voltage $\mathrm{V}_{\mathrm{MPL}}$, proportional to the input power can be obtained.
In effect,

$$
V_{M P L}=R_{M P L} \times k_{M P L} \times V_{c s}^{2} \times \frac{(\mathrm{Sf})}{T}
$$

where: $\mathrm{k}_{\mathrm{MPL}}$ is the multiplier gain
(Sf) is the width of the calibrated pulse
T is the switching (oscillator) period
Now, as Sf is built comparing the oscillator to a constant level, (Sf) is proportional to $\mathrm{R}_{\text {ref }}$ and $\mathrm{C}_{\mathrm{T}}$ :

$$
(\mathrm{Sf})=\mathrm{k} 1 \times \mathrm{R}_{\mathrm{ref}} \times \mathrm{C}_{\mathrm{T}}
$$

where: k 1 is a constant
On the other hand, $\mathrm{k}_{\mathrm{MPL}}$ that is depending on the reference current source $I_{\text {ref }}$, is proportional to $1 / \mathrm{R}_{\text {ref }}$ :

$$
\mathrm{k}_{\mathrm{MPL}}=\mathrm{k} 2 \times \frac{1}{\mathrm{R}_{\mathrm{ref}}}
$$

where: k 2 is a constant
So:

$$
\mathrm{V}_{\mathrm{MPL}}=\mathrm{R}_{\mathrm{MPL}} \times \mathrm{k} 1 \times \mathrm{k} 2 \times \mathrm{Vcs}^{2} \times \mathrm{f} \times \mathrm{C}_{\mathrm{T}}
$$

where: $\mathrm{C}_{\mathrm{T}}$ is the oscillator capacitor
Finally:

$$
\mathrm{V}_{\mathrm{MPL}}=\mathrm{R}_{\mathrm{MPL}} \times \Gamma_{\mathrm{MPL}} \times \mathrm{Vcs}^{2} \times \mathrm{f} \times \mathrm{C}_{\mathrm{T}}
$$

where: $\Gamma_{\mathrm{MPL}}$ is the MPL parameter as defined in the specification. This is a constant equal to the product (k1 x k2).

Now, as:

$$
\operatorname{Pin}=\frac{1}{2} \times L_{P} \times \mathrm{lpk}^{2} \times f
$$

and:

$$
\mathrm{Vcs}=\mathrm{R}_{\mathrm{S}} \times \mathrm{lpk}
$$

So:

$$
\mathrm{V}_{\mathrm{MPL}}=\frac{2 \times \mathrm{R}_{\mathrm{MPL}} \times \Gamma_{M P L} \times \mathrm{C}_{\mathrm{T}} \times \mathrm{R}_{\mathrm{S}}^{2}}{\mathrm{~L}_{\mathrm{P}}} \times \operatorname{Pin}
$$

A comparator is used to compare $\mathrm{V}_{\text {MPL }}$ to $\mathrm{V}_{\text {ref }}$, the output of which, Dis ${ }_{\text {MPL }}$, is connected to the "definitive inhibition latch" of the disabling block. So, when the calculated power is higher than the threshold, the circuit is definitively disabled (the system considers that there is an overload condition).

Finally, replacing $\mathrm{V}_{\mathrm{MPL}}$ by 2.5 V (the threshold value), the $\mathrm{R}_{\text {MPL }}$ value to be used, can be deducted:

$$
\mathrm{R}_{\mathrm{MPL}}=\frac{1.25 \times \mathrm{L}_{\mathrm{P}}}{\Gamma_{\mathrm{MPL}} \times \mathrm{C}_{\mathrm{T}} \times \mathrm{R}_{\mathrm{S}}^{2} \times(\mathrm{Pin})_{\max }}
$$

Figure 14. OHD and MPL

## Overheating Detection Section (O.H.D.)

In the MPL block, the converter input power is calculated. In the O.H.D. block, that is the power MOSFET heating which is calculated, using the following equation:

$$
\mathrm{p}_{\mathrm{on}}=\frac{1}{3} \times \mathrm{R}_{\mathrm{dson}} \times \mathrm{lpk}^{2} \times \mathrm{d}
$$

where: $\mathrm{p}_{\text {on }}$ are the power switch on-time losses
$\mathrm{R}_{\mathrm{dson}}$ is the conduction MOSFET resistor d is the duty cycle

As in the MPL section, the squared Ipk term is estimated by building a current source proportional to $\mathrm{Vcs}^{2}$.

The duty cycle is taken into account thanks to the action on this current source of a "chopper" controlled by the circuit output. By this means, the pin 6 average current is proportional to the squared peak current multiplied to the duty cycle (refer to Figure 14).

So, using an external resistor and capacitor network ( $\mathrm{R}_{\mathrm{OHD}}, \mathrm{C}_{\mathrm{OHD}}$ ) on this pin, a voltage $\mathrm{V}_{\mathrm{OHD}}$, proportional to the conduction losses can be obtained.

Like in the MPL block, this voltage $\mathrm{V}_{\mathrm{OHD}}$, is compared to 2.5 V . If $\mathrm{V}_{\mathrm{OHD}}$ gets higher than this threshold, the disabling block is activated by $\mathrm{Dis}_{\mathrm{OHD}}$ (output of the comparator).

The external resistor $\mathrm{R}_{\mathrm{OHD}}$ choice enables to obtain a calculated $\mathrm{V}_{\mathrm{OHD}}$ equal to 2.5 V when the conduction losses are equal to their maximum value.
In effect,

$$
\mathrm{v}_{\mathrm{OHD}}=\mathrm{R}_{\mathrm{OHD}} \times \mathrm{k}_{\mathrm{OHD}} \times \mathrm{Vcs}^{2} \times \mathrm{d}
$$

where: $\mathrm{k}_{\mathrm{OHD}}$ is the multiplier gain
Now, as $\mathrm{k}_{\mathrm{OHD}}$ that is depending on the reference current source $I_{\text {ref }}$, is proportional to $1 / R_{\text {ref }}$ :

$$
\mathrm{k}_{\mathrm{OHD}}=\mathrm{k} 2 \times \frac{1}{\mathrm{R}_{\text {ref }}}
$$

where: k 2 is a constant
So:

$$
\mathrm{v}_{\mathrm{OHD}}=\mathrm{R}_{\mathrm{OHD}} \times \mathrm{k} 2 \times \frac{\mathrm{Vcs}^{2}}{\mathrm{R}_{\mathrm{ref}}} \times \mathrm{d}
$$

Finally:

where: $\Gamma_{\mathrm{OHD}}$ is the OHD parameter as defined in the specification. This is a constant equal to k 2 .

Now, as:

$$
\mathrm{Vcs}=\mathrm{R}_{\mathrm{S}} \times \mathrm{lpk}
$$

So, replacing Vcs and using the $p_{o n}$ equation:

$$
\mathrm{V}_{\mathrm{OHD}}=\frac{3 \times \mathrm{R}_{\mathrm{OHD}} \times \Gamma_{\mathrm{OHD}} \times \mathrm{R}_{\mathrm{S}}^{2}}{\mathrm{R}_{\mathrm{ref}} \times \mathrm{R}_{\mathrm{dson}}} \times \mathrm{p}_{\mathrm{on}}
$$

So, by choosing the value of $\mathrm{R}_{\mathrm{OHD}}$, the heating corresponding to $\mathrm{V}_{\text {ref }}$ is determined. If the MOSFET dissipation is such that the heating is higher than this threshold, the "definitive inhibition latch" of the Disabling Block is activated and so, the output gets definitively disabled.

Consequently, by replacing $\mathrm{V}_{\mathrm{OHD}}$ by 2.5 V (threshold value) in the last equation, the value $\mathrm{R}_{\mathrm{OHD}}$ to use, can be deducted:

$$
\mathrm{R}_{\mathrm{OHD}}=\frac{2.5 \times \mathrm{R}_{\mathrm{ref}} \times \mathrm{R}_{\mathrm{dson}}}{3 \times \Gamma_{\mathrm{OHD}} \times \mathrm{R}_{\mathrm{S}}^{2} \times\left(\mathrm{p}_{\mathrm{On}}\right)_{\mathrm{max}}}
$$

where: $\left(\mathrm{p}_{\mathrm{on}}\right)_{\max }$ are the maximum on time losses that are acceptable.

## Disabling Block Section

This section consists of a "definitive inhibition latch" (directly supplied by the $\mathrm{V}_{\mathrm{cc}}$ ) that disables the output (the output is forced to zero).

In effect, this block aims at definitively disabling the circuit when one of the following faults is detected:

- a Winding Short Circuit
- too high synchronization pulses
- a too high input power
- a too high power switch (MOSFET) heating

The signals corresponding to these faults are high when a fault is detected (for instance, when the input power is detected as too high, Dis MPL is high).

When one (or several) of these four faults is detected, a current source charges $\mathrm{C}_{\text {ext }}$ (with a certain duty cycle) and when its voltage becomes higher than $\mathrm{V}_{\text {ref }}$, the definitive inhibition latch is activated. Thus, the circuit gets definitively disabled after a delay depending on $\mathrm{C}_{\text {ext }}$.

According to the detected fault, the current that charges $\mathrm{C}_{\text {ext }}$ is not the same:

The typical values are:

- $260 \mu \mathrm{~A}$ for EHTOVP and WSCD
- $8.5 \mu \mathrm{~A}$ for OHD and MPL
when $\mathrm{R}_{\text {ref }}$ is equal to $10 \mathrm{k} \Omega$.

Figure 15. Disabling Block
This latch is reset when the $\mathrm{V}_{\mathrm{cc}}$ falls down to about 3.0 V . In this case, if a new startup is performed, the circuit will work normally (until this fault or another one is detected).

Practically, to re-start after a fault has shutdown the circuit, the converter must be turned off for a time long enough to enable the $\mathrm{V}_{\mathrm{cc}}$ capacitor discharge (repair time...).
Note: As $\mathrm{V}_{\text {WSCD }}$ is generally a really narrow pulse, it is necessary to add a latch and a delay to build a $4 \mu$ s width pulse when $V_{\text {WSCD }}$ becomes high.

## Application Schematic

65 W output SMPS controlled by the MC44605
Mains input range: 90 Vac <-> 264 Vac
Synchronization range: $\mathbf{3 0} \mathbf{~ k H z}$ <-> 100 kHz
Orega Transformer ref. G5984-00
( $L p=195 \mu \mathrm{H}$ )

## MC44605

Performances
