

FEATURES

**Low Cost 3.3 V CMOS MxFE™ for
MCNS-DOCSIS, DVB-, DAVIC-Compliant
Set-Top Box and Cable Modem Applications**
232 MHz Quadrature Digital Upconverter
12-Bit Direct IF DAC (TxDAC+®)
Up to 65 MHz Carrier Frequency DDS
Programmable Sampling Clock Rates
Selectable Interpolation Filter
Analog Tx Output Level Adjust
12-Bit, 33 MSPS Direct IF ADC
Dual 8-Bit, 16.5 MSPS Sampling IQ ADCs
Two 12-Bit Σ - Δ Auxiliary DACs
**Direct Interface to AD8321/AD8325 or AD8322/AD8327
PGA Cable Driver**

APPLICATIONS

Cable Modems
Set-Top Boxes
Wireless Modems

GENERAL DESCRIPTION

The AD9877 is a single-supply cable modem/set-top box mixed-signal front end. The device contains a transmit path interpolation filter, a complete quadrature digital upconverter, and a transmit DAC. The receive path contains a 12-bit ADC and dual 8-bit ADCs. All internally required clocks and an output system clock are generated by the PLL from a single crystal or clock input.

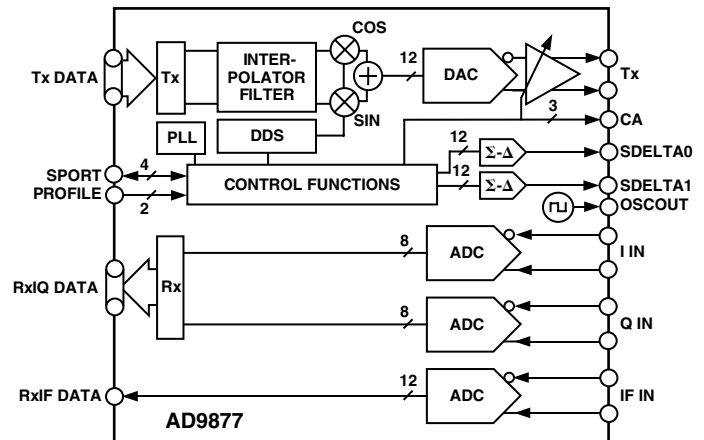

The transmit path interpolation filter provides upsampling factors of $12\times$ or $16\times$ with an output signal bandwidth as high as 5.8 MHz. Carrier frequencies up to 65 MHz with 26 bits of frequency tuning resolution can be generated by the direct digital synthesizer (DDS). The transmit DAC resolution is 12 bits and can run at sampling rates as high as 232 MSPS. Analog output scaling from 0 dB to 7.5 dB in 0.5 dB steps is available to preserve SNR when reduced output levels are required.

MxFE is a trademark of Analog Devices, Inc.
TxDAC+ is a registered trademark of Analog Devices, Inc.

REV. A

Information furnished by Analog Devices is believed to be accurate and reliable. However, no responsibility is assumed by Analog Devices for its use, nor for any infringements of patents or other rights of third parties that may result from its use. No license is granted by implication or otherwise under any patent or patent rights of Analog Devices.

FUNCTIONAL BLOCK DIAGRAM

The 12-bit ADC has excellent undersampling performance, allowing it to deliver better than 10 ENOBs with IF inputs up to 70 MHz. The 12-bit IF ADC can sample at a rate up to 33 MHz, allowing it to process wideband signal inputs.

Two programmable sigma-delta DACs are available and can be used to control external components, such as variable gain amplifiers (VGAs) or voltage-controlled tuners.

The AD9877 integrates a CA port that enables a host processor to control the AD8321/AD8325 or AD8322/AD8327 programmable gain amplifier (PGA) cable drivers via the MxFE SPORT.

The AD9877 is available in a 100-lead MQFP package. It offers enhanced receive path undersampling performance and lower cost, compared to the pin-compatible AD9873. The AD9877 is specified over the extended industrial (-40°C to $+85^{\circ}\text{C}$) temperature range.

AD9877—SPECIFICATIONS

($V_{AS} = 3.3\text{ V} \pm 5\%$, $V_{DS} = 3.3\text{ V} \pm 10\%$, $f_{OSCIN} = 27\text{ MHz}$, $f_{SYSCLK} = 216\text{ MHz}$, $f_{MCLK} = 54\text{ MHz}$ ($M = 8$ and $N = 4$). ADC sample frequencies derived from PLL (f_{MCLK}), $R_{SET} = 4.02\text{ k}\Omega$, max. fine gain, $75\ \Omega$ DAC load.)

ABSOLUTE MAXIMUM RATINGS*

Power Supply (V _{AVDD} , V _{DVDD} , V _{DRVDD})	3.9 V
Digital Output Current	5 mA
Digital Inputs	-0.3 V to DRVDD + 0.3 V
Analog Inputs	-0.3 V to AVDD + 0.3 V
Operating Temperature	-40°C to +85°C
Maximum Junction Temperature	150°C
Storage Temperature	-65°C to +150°C
Lead Temperature (Soldering 10 sec)	300°C

*Absolute maximum ratings are limiting values, to be applied individually, and beyond which the serviceability of the circuit may be impaired. Functional operability under any of these conditions is not necessarily implied. Exposure to absolute maximum rating conditions for extended periods of time may affect device reliability.

EXPLANATION OF TEST LEVELS

- I Devices are 100% production tested at 25°C and guaranteed by design and characterization testing for industrial operating temperature range (-40°C to +85°C).
- II Parameter is guaranteed by design and/or characterization testing.
- III Parameter is a typical value only.
- N/A Test level definition is not applicable.

THERMAL CHARACTERISTICS

Thermal Resistance

ORDERING GUIDE

Model	Temperature Range	Package Description	Package Option
AD9877ABS	-40°C to +85°C	100-MQFP	S-100C

CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the AD9877 features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

			100	NC	No Connect (Leave Floating)

AD9877

DEFINITIONS OF SPECIFICATIONS

APERTURE DELAY

The aperture delay is a measure of the sample-and-hold amplifier (SHA) performance and specifies the time delay between the rising edge of the sampling clock input to when the input signal is held for conversion.

APERTURE UNCERTAINTY (JITTER)

Aperture jitter is the variation in aperture delay for successive samples and is manifested as noise on the input to the ADC.

CHANNEL-TO-CHANNEL ISOLATION (CROSSTALK)

In an ideal multichannel system, the signal in one channel will not influence the signal level of another channel. The channel-to-channel isolation specification is a measure of the change that occurs to a grounded channel as a full-scale signal is applied to another channel.

DIFFERENTIAL NONLINEARITY ERROR (DNL, NO MISSING CODES)

An ideal converter exhibits code transitions that are exactly 1 LSB apart. DNL is the deviation from this ideal value. Guaranteed no missing codes to 10-bit resolution indicates that all 1,024 codes, respectively, must be present over all operating ranges.

EFFECTIVE NUMBER OF BITS (ENOB)

For a sine wave, SINAD can be expressed in terms of the number of bits. Using the following formula:

$$N = (\text{SINAD} - 1.76 \text{ dB})/6.02$$

It is possible to get a measure of performance expressed as N , the effective number of bits. Thus, the effective number of bits for a device for sine wave inputs at a given input frequency can be calculated directly from its measured SINAD.

GAIN ERROR

The first code transition should occur at an analog value one-half LSB above full scale. The last transition should occur for an analog value 1 1/2 LSB below the nominal full scale. Gain error is the deviation of the actual difference between the first and last code transitions and the ideal difference between the first and last code transitions.

INPUT REFERRED NOISE

The rms output noise is measured using histogram techniques. The ADC output code's standard deviation is calculated in LSB and converted to an equivalent voltage. This results in a noise figure that can be directly referred to the input of the MxFE.

INTEGRAL NONLINEARITY ERROR (INL)

Linearity error refers to the deviation of each individual code from a line drawn from the negative full scale through the positive full scale. The point used as the negative full scale occurs 1/2 LSB before the first code transition. The positive full scale is defined as a level 1 1/2 LSB beyond the last code transition. The deviation is measured from the middle of each particular code to the true straight line.

OFFSET ERROR

First transition should occur for an analog value 1/2 LSB above -FS. Offset error is defined as the deviation of the actual transition from that point.

OUTPUT COMPLIANCE RANGE

The range of allowable voltage at the output of a current-output DAC. Operation beyond the maximum compliance limits may cause either output stage saturation or breakdown, resulting in nonlinear performance.

PHASE NOISE

Single sideband phase noise power is specified relative to the carrier (dBc/Hz) at a given frequency offset (1 kHz) from the carrier. Phase noise can be measured directly in single-tone transmit mode with a spectrum analyzer that supports noise marker measurements. It detects the relative power between the carrier and the offset (1 kHz) sideband noise and takes the resolution bandwidth (rbw) into account by subtracting $10 \log(\text{rbw})$. It also adds a correction factor that compensates for the implementation of the resolution bandwidth, log display, and detector characteristic.

PIPELINE DELAY (LATENCY)

The number of clock cycles between conversion initiation and the associated output data being made available.

POWER SUPPLY REJECTION

Power supply rejection specifies the converter's maximum full-scale change when the supplies are varied from nominal to minimum and maximum specified voltages.

SIGNAL-TO-NOISE AND DISTORTION (SINAD) RATIO

SINAD is the ratio of the rms value of the measured input signal to the rms sum of all other spectral components below the Nyquist frequency, including harmonics but excluding dc. The value for SINAD is expressed in decibels.

SIGNAL-TO-NOISE RATIO (SNR)

SNR is the ratio of the rms value of the measured input signal to the rms sum of all other spectral components below the Nyquist frequency, excluding harmonics and dc. The value for SNR is expressed in decibels.

SPURIOUS-FREE DYNAMIC RANGE (SFDR)

The difference, in dB, between the rms amplitude of the DAC's output signal (or ADC's input signal) and the peak spurious signal over the specified bandwidth (Nyquist bandwidth unless otherwise noted).

TOTAL HARMONIC DISTORTION (THD)

THD is the ratio of the rms sum of the first six harmonic components to the rms value of the measured input signal and is expressed as a percentage or in decibels.

*Register bits denoted with "0" must be programmed with a "0" every time that register is written.

AD9877

REGISTER BIT DEFINITIONS

REGISTER 00—Initialization

Bits 0 to 4: OSCIN Multiplier

This register field is used to program the on-chip multiplier (PLL) that generates the chip's high frequency system clock f_{SYSCLK} .

For example, to multiply the external crystal clock f_{OSCIN} by 16 decimals, program Register 0, Bits 4:0 as 0x10. The default value of M is 0x08. Valid entries range from $M = 1-31$. When M is chosen equal to 1, the PLL is disabled. All internal clocks are derived directly from OSCIN.

The PLL requires 200 MCLK cycles to regain frequency lock after a change in M, the clock multiplier value. After the recapture time of the PLL, the frequency of f_{SYSCLK} is stable.

For timing integrity, certain restrictions on the values of M and N apply when both AD9877 transmit and receive paths are used.

The supported modes are:

ADC Clock Select	N	M
1, f_{OSCIN}	3	6
	4	8
0, f_{MCLK} (PLL Derived)	3	12
	4	16

Bit 5: RESET

Writing a 1 to this bit resets the registers to their default values and restarts the chip. The RESET Bit always reads back 0. The bits in Register 0 are not affected by this software reset. However, a low level at the RESET pin would force all registers, including all bits in Register 0, to their default state.

Bit 6: LSB First

Active high indicates SPI serial port access of instruction byte and data registers is least significant bit (LSB) first. Default low indicates most significant bit (MSB) first format.

Bit 7: SDIO Bidirectional

Active high configures serial port as a three-signal port with the SDIO pin used as a bidirectional input/output pin. Default low indicates the serial port uses four signals with SDIO configured as an input and SDO configured as an output.

REGISTER 01—Clock Configuration

Bits 0 to 5: MCLK Divider

This register determines the output clock on the OSCOUT pin. At default zero ($R = 0$), OSCOUT provides a buffered version of the OSCIN clock signal for other chips.

The register can also be used to divide the chip's master clock, f_{MCLK} , by R, where R is an integer between 2 and 63. The generated reference clock on the OSCOUT pin can be used for external frequency controlled devices.

Bit 6: SYSCLK Divider

The OSCIN multiplier output clock, f_{SYSCLK} , can be divided by 4 or 3 to generate the chip's master clock. Active high indicates a divide ratio of $N = 3$. Default low configures a divide ratio of $N = 4$.

Bit 7: PLL Lock Detect

When this bit is set low, the OSCOUT pin functions in its default mode and provides an output clock with frequency $f_{\text{MCLK/R}}$ as described above.

If this bit is set to 1, the OSCOUT pin is configured to indicate whether the PLL is locked to f_{OSCIN} . In this mode, the OSCOUT pin should be low-pass filtered with an RC filter of 1.0 k Ω and 0.1 μF . A high output on OSCOUT indicates the PLL has achieved lock with f_{OSCIN} .

REGISTER 02—Power-Down

Sections of the chip that are not used can be powered down when the corresponding bits are set high. This register has a default value of 0x00; all sections active.

Bit 0: Power-Down 8-Bit ADC

Active high powers down the 8-bit ADC.

Bit 3: Power-Down 12-Bit ADC Reference

Active high powers down the 12-bit ADC reference.

Bit 4: Power-Down 12-Bit ADC

Active high powers down the 12-bit ADC.

Bit 5: Power-Down Digital Tx

Active high powers down the digital transmit section of the chip, similar to the function of the PWRDN pin.

Bit 6: Power-Down DAC Tx

Active high powers down the DAC.

Bit 7: Power-Down PLL

Active high powers down the OSCIN multiplier.

REGISTER 03 to 06—Sigma-Delta Control Words

The sigma-delta control words are 12 bits wide and split in MSB Bits [11:4] and LSB Bits [3:0]. Changes to the sigma-delta control words take effect immediately for every MSB or LSB register write. Sigma-delta output control words have a default value of "0." The control words are in straight binary format, with 0x000 corresponding to the bottom of the scale and 0xFFFF corresponding to the top of the scale (see Figure 5 for details).

If Flag Enable (Bit 0 of Register 3 or 5) is set high, the SDELTA pins will maintain a fixed logic level determined directly by the MSB of the sigma-delta control word.

REGISTER 08—ADC Clock Configuration

Bit 4: Power-Down RxSYNC and 8-Bit ADC Clock

Setting this bit to 1 powers down the 8-bit ADC's sampling clock and stops the RxSYNC output pin. It can be used for additional power-saving on top of the power-down selections in Register 2.

Bit 7: ADC Clock Select

When set high, the input clock at OSCIN is used directly as the ADC sampling clock. When set low, the internally generated master clock, MCLK, is used as the ADC sampling clock. Best ADC performance is achieved when the ADCs are sampled directly from f_{OSCIN} using an external crystal or low jitter crystal oscillator.

REGISTER 0C—Die Revision

Bits 0 to 3: Version

The die version of the chip can be read from this register.

REGISTER 0D—Tx Frequency Tuning Words LSBs

This register accommodates two least significant bits for each of the four frequency tuning words (see description of Burst Parameter below).

REGISTER 0E—DAC Gain Control

This register allows the user to program the DAC gain if Tx Gain Control Select Bit 3 in Register F is set to 0.

Bits [3:0]	DAC Gain
0000	0.0 dB (Default)
0001	0.5 dB
0010	1.0 dB
0011	1.5 dB
...	...
1110	7.0 dB
1111	7.5 dB

REGISTER 0F—Tx Path Configuration**Bit 0: Single-Tone Tx Mode**

Active high configures the AD9877 for single-tone applications (e.g., FSK). The AD9877 will supply a single frequency output as determined by the frequency tuning word selected by the active profile. In this mode, the TxIQ input data pins are ignored but should be tied to a valid logic voltage level. Default value is 0 (inactive).

Bit 1: Spectral Inversion Tx

When set to 1, inverted modulation is performed.

$$MODULATOR_OUT = [I \cos(\omega t) + Q \sin(\omega t)]$$

Default is logic zero, noninverted modulation.

$$MODULATOR_OUT = [I \cos(\omega t) - Q \sin(\omega t)]$$

Bit 3: CA Interface Mode Select

This bit changes the manner in which transmit gain control is performed. Typically, either AD8321/AD8325 (default 0) or AD8322/AD8327 (default 1) variable gain cable amplifiers are programmed over the chip's 3-wire cable amplifier (CA) interface. The Tx gain control select changes the interpretation of the bits in Registers 13, 17, 1B, and 1F (see Cable Driver Gain Control section).

Bit 4 and 5: Profile Select

The AD9877 quadrature digital upconverter is capable of storing four preconfigured modulation modes called profiles. Each profile defines a transmit frequency tuning word and cable driver amplifier gain (/DAC gain) setting. Profile Select [1:0] Bits or PROFILE [1:0] pins program the current register profile to be used. Profile Select bits should always be "0" if PROFILE[1:0] pins are used to switch between profiles. Using the Profile Select Bits as a means of switching between different profiles requires the PROFILE [1:0] pins to be tied low.

REGISTERS 10 through 1F: Burst Parameter**Tx Frequency Tuning Words**

The frequency tuning word (FTW) determines the DDS-generated carrier frequency (f_C) and is formed via a concatenation of register addresses.

The 26-bit FTW is spread over four register addresses. Bit 25 is the MSB and Bit 0 is the LSB.

The carrier frequency equation is given as:

$$f_C = [FTW \times f_{SYSCLK}] / 2^{26}$$

where $f_{SYSCLK} = M \times f_{OSCIN}$ and $FTW < 0x2000000$.

Changes to FTW bytes take effect immediately.

Cable Driver Gain Control

The AD9877 has a three-pin interface to the AD832x family of programmable gain cable driver amplifiers. This allows direct control of the cable driver's gain through the AD9877.

In its default mode, the complete 8-bit register value is transmitted over the 3-wire CA interface.

If Bit 3 of Register F is set high, Bits [7:4] determine the 8-bit word sent over the CA interface according to the table below.

Bits [7:4]	CA Interface Transmit Word
0000	0000 0000 (Default)
0001	0000 0001
0010	0000 0010
0011	0000 0100
0100	0000 1000
0101	0001 0000
0110	0010 0000
0111	0100 0000
1000	1000 0000

In this mode, the lower bits determine the fine gain setting of the DAC output.

Bits [3:0]	DAC Fine Gain
0000	0.0 dB (Default)
0001	0.5 dB
0010	1.0 dB
0011	1.5 dB
...	...
1110	7.0 dB
1111	7.5 dB

New data is automatically sent over the 3-wire CA interface (and DAC gain adjust) whenever the value of the active gain control register changes or a new profile is selected. The default value is 0x00 (lowest gain).

The formula for the combined output level calculation of the AD9877 fine gain and the AD8327 or AD8322 coarse gain is:

$$V_{8327} = V_{9877(0)} + (fine)/2 + 6(coarse) - 19$$

$$V_{8322} = V_{9877(0)} + (fine)/2 + 6(coarse) - 14$$

where

$fine$ = the decimal value of Bits [3:0].

$coarse$ = the decimal value of Bits [7:8].

$V_{9877(0)}$: the level at AD9877 output in dBmV for $fine = 0$.

V_{8327} : the level at output of the AD8327 in dBmV.

V_{8322} : the level at output of the AD8322 in dBmV.

AD9877—Typical Performance Characteristics ($V_{AS} = 3.3\text{ V}$, $V_{DS} = 3.3\text{ V}$, $f_{OSCIN} = 27\text{ MHz}$, $f_{SYSCLK} = 216\text{ MHz}$, $f_{MCLK} = 54\text{ MHz}$ ($M = 8$ and $N = 4$). ADC sample rate derived directly from f_{OSCIN} , $R_{SET} = 4.02\text{ k}\Omega$ ($I_{OUT} = 10\text{ mA}$), and $75\text{ }\Omega$ DAC load, unless otherwise noted.)

AD9877

THEORY OF OPERATION

To gain a general understanding of the AD9877, it is helpful to refer to Figure 1, which displays a block diagram of the device architecture. The following is a general description of the device functionality. Later sections will detail each of the data path building blocks.

Transmit Section

Modulation Mode Operation

The AD9877 accepts 6-bit words that are strobed synchronous to the master clock, MCLK, into the data assembler. A high level on TxSYNC signals the start of a transmit symbol. Two successive 6-bit words form a 12-bit symbol component. The incoming data is assumed to be complex, in that alternating 12-bit words are regarded as the in-phase (I) and quadrature (Q) components of a symbol. Symbol components are assumed to be in two's complement format. The rate at which the TxIQ data is read will be referred to as the master clock rate (f_{MCLK}).

The data assembler receives the multiplexed IQ data and creates two parallel 12-bit paths with I and Q data pairs, which comprise a complex symbol. The rate at which the I and Q data word pairs appear at the output of the data assembler will be referred to as the IQ sample rate (f_{IQCLK}). Because four 6-bit reads are required at the TxIQ input to read a full 24-bit complex symbol, f_{MCLK} is 4 times the IQ sample rate ($f_{MCLK} = 4 \times f_{IQCLK}$).

Once through the data assembler, the IQ data streams are fed through two half-band filters (half-band filters #1 and #2). The combination of these two filters results in the sample rate increasing by a factor of 4. Thus, at the output of half-band filter #2, the sample rate is $4 \times f_{IQCLK}$. In addition to the sample rate increase, the half-band filters provide the low-pass filtering characteristic necessary to suppress the spectral images produced by the upsampling process.

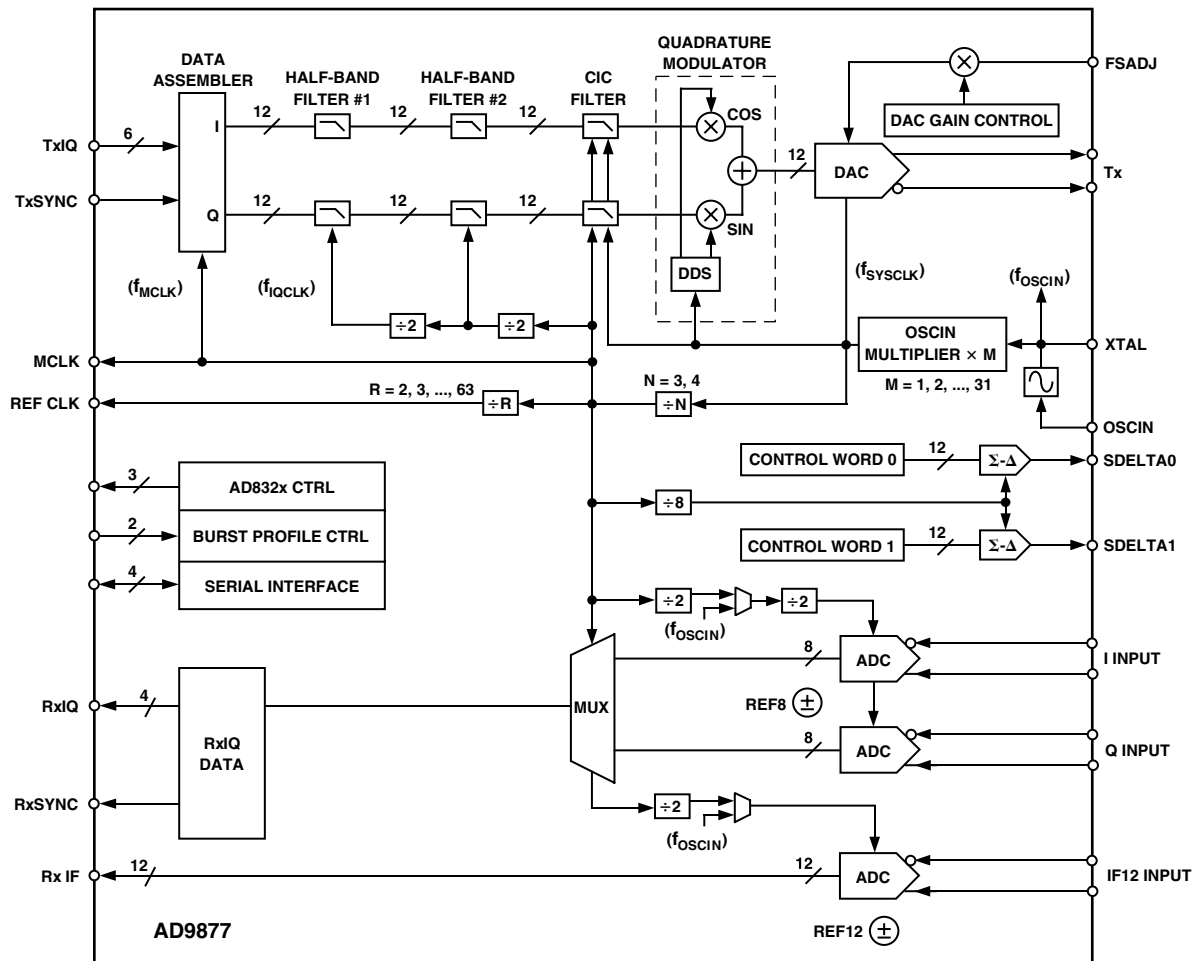

Figure 1. Block Diagram

After passing through the half-band filter stages, the IQ data streams are fed to a cascaded integrator-comb (CIC) filter. This filter is configured as an interpolating filter, which allows further upsampling rates of 3 or 4. The CIC filter, like the half-bands, has a built-in low-pass characteristic. Again, this provides for suppression of the spectral images produced by the upsampling process.

The digital quadrature modulator stage following the CIC filters is used to frequency shift (upconvert) the baseband spectrum of the incoming data stream up to the desired carrier frequency.

The carrier frequency is controlled numerically by a direct digital synthesizer (DDS). The DDS uses the internal system clock (f_{SYSCLK}) to generate the desired carrier frequency with a high degree of precision. The carrier is applied to the I and Q multipliers in quadrature fashion (90° phase offset) and summed to yield a data stream that is the modulated carrier.

It should be noted at this point that the incoming data has been converted from an input sample rate of f_{MCLK} to an output sample rate of f_{SYSCLK} (see Figure 1). The modulated carrier becomes the 12-bit samples sent to the DAC.

Single-Tone Output Transmit Operation

The AD9877 can be configured for frequency synthesis applications by writing the single-tone bit true. In single-tone mode, the AD9877 disengages the modulator and preceding data path logic to output a spectrally pure single frequency sine wave. The AD9877 provides for a 26-bit frequency tuning word, which results in a tuning resolution of 3.2 Hz at a f_{SYSCLK} rate of 216 MHz. A good rule of thumb when using the AD9877 as a frequency synthesizer is to limit the fundamental output frequency to 30% of f_{SYSCLK} . This avoids generating aliases too close to the desired fundamental output frequency, thus minimizing the cost of filtering the aliases.

Frequency hopping via the PROFILE inputs and associated tuning word is also supported in single-tone mode, which allows frequency shift keying (FSK) modulation.

OSCIN Clock Multiplier

As mentioned earlier, the output data is sampled at the rate of f_{SYSCLK} . The AD9877 has a built-in programmable clock multiplier and an oscillator circuit. This allows the use of a relatively low frequency, thus less expensive, crystal or oscillator to generate the OSCIN signal. The low frequency OSCIN signal can then be multiplied in frequency by an integer factor of between 1 and 31, inclusive, to become the f_{SYSCLK} clock.

For DDS applications, the carrier is typically limited to about 30% of f_{SYSCLK} . For a 65 MHz carrier, the system clock required is above 216 MHz.

The OSCIN multiplier function maintains clock integrity as evidenced by the AD9877's excellent phase noise characteristics and low clock-related spur in the output spectrum. External loop filter components consisting of a series resistor (1.3 k Ω) and capacitor (0.01 μF) provide the compensation zero for the OSCIN multiplier PLL loop. The overall loop performance has been optimized for these component values.

Receive Section

The AD9877 includes three high speed, high performance ADCs. Two matched 8-bit ADCs are optimized for analog IQ demodulated signals and can be sampled at rates up to 16.5 MSPS. A direct IF 12-bit ADC can sample signals at rates up to 33 MSPS.

The ADC sampling frequency can be derived directly from the OSCIN signal or from the on-chip OSCIN multiplier. For highest dynamic performance, it is recommended to choose an OSCIN frequency that can be directly used as the ADC sampling clock. Digital 8-bit ADC outputs are multiplexed to one 4-bit bus, clocked by the master clock (MCLK). The 12-bit ADC uses a nonmultiplexed 12-bit interface with an output data rate of half f_{MCLK} frequency.

AD9877

Clock and Oscillator Circuitry

The AD9877's internal oscillator generates all sampling clocks from a simple, low cost, parallel resonance, fundamental frequency quartz crystal. Figure 2 shows how the quartz crystal is connected between OSCIN (Pin 61) and XTAL (Pin 60) with parallel resonant load capacitors as specified by the crystal manufacturer. The internal oscillator circuitry can also be overdriven by a clock applied to OSCIN with XTAL left unconnected.

$$f_{OSCIN} = f_{MCLK} \times N/M$$

An internal phase-locked loop (PLL) generates the DAC sampling frequency, f_{SYSCLK} , by multiplying OSCIN frequency M times. The MCLK signal (Pin 23) f_{MCLK} is derived by dividing this PLL output frequency by N (Register Address 01h).

$$f_{SCYCLK} = f_{OSCIN} \times M$$

$$f_{MCLK} = f_{OSCIN} \times M/N$$

An external PLL loop filter (Pin 57) consisting of a series resistor and ceramic capacitor (Figure 2, R1 = 1.3 kΩ, C12 = 0.01 μF) is required for stability of the PLL. Also, a shield surrounding these components is recommended to minimize external noise coupling into the PLL's voltage-controlled oscillator input (guard trace connected to AVDDPLL).

Figure 1 shows that ADCs are either sampled directly by a low jitter clock at OSCIN or by a clock that is derived from the PLL output. Operating modes can be selected in Register 8. Sampling the ADCs directly with the OSCIN clock requires MCLK to be programmed at twice the OSCIN frequency.

Figure 2. Basic Connections Diagram

PROGRAMMABLE CLOCK OUTPUT REF CLK

The AD9877 provides a frequency-programmable clock output OSCOUT (Pin 71). OSCIN or MCLK (f_{MCLK}) and the master clock divider ratio R stored in Register Address 01h determine its frequency:

$$f_{OSCOUT} = f_{MCLK} / R \text{ or } f_{OSCIN}$$

In its default setting (0x00 in Register 1), the OSCOUT pin provides a buffered output of f_{OSCIN} .

RESET AND TRANSMIT POWER-DOWN

Power-Up Sequence

On initial power-up, the $\overline{\text{RESET}}$ pin should be held low until the power supply is stable.

Once $\overline{\text{RESET}}$ is de-asserted, the AD9877 can be programmed over the serial port. It is recommended that the $\overline{\text{PWRDN}}$ pin be held low during the reset. Changes to ADC Clock Select (Register 08h) or SYS Clock Divider N (Register 01) should be programmed before the rising edge of $\overline{\text{PWRDN}}$. Changes to the multiplier (M) will require the PLL to reacquire the new frequency and may take up to 1 ms.

Once the PLL is frequency-locked and after the $\overline{\text{PWRDN}}$ pin is brought high, transmit data can be sent reliably.

If the $\overline{\text{PWRDN}}$ pin cannot be held low throughout the reset and PLL settling time period, then the Power-Down Digital Tx Bit or the $\overline{\text{PWRDN}}$ pin should be pulsed after the PLL has settled. This will ensure correct transmit filter initialization.

RESET

To initiate hardware reset, the $\overline{\text{RESET}}$ pin should be held low for at least 100 ns. All internally generated clocks but OSCOUT stop during reset. The MCLK signal begins transmission three

clock cycles after reset. The rising edge of $\overline{\text{RESET}}$ reinitializes the programmable registers to their default values. The same sequence as described in the Power-Up Sequence section should be followed after a reset or change in M .

A software reset (writing a 1 into Bit 5 of Register 00) is functionally equivalent to the hardware reset but does not force Register 00 to its default value.

Figure 3. Power-Up Sequence for Tx Data Path

Transmit Power-Down

A low level on the $\overline{\text{PWRDN}}$ pin stops all clocks linked to the digital transmit data path and resets the CIC filter. De-asserting $\overline{\text{PWRDN}}$ reactivates all clocks. The CIC filter is held in a reset state for 80 MCLK cycles after the rising edge of $\overline{\text{PWRDN}}$ to allow for flushing of the half-band filters with new input data.

Transmit data bursts should be padded with at least 20 symbols of null data directly before the $\overline{\text{PWRDN}}$ pin is asserted. Immediately after the $\overline{\text{PWRDN}}$ pin is de-asserted, the transmit burst should start with a minimum of 20 null data symbols. This avoids unintended DAC output samples caused by the transmit path latency and filter settling time.

Software Power-Down Digital Tx (Bit 5 in Register 02) is functionally equivalent to the hardware $\overline{\text{PWRDN}}$ pin and takes effect immediately after the last register bit has been written over the serial port.

Figure 4. Timing Sequence to Flush Tx Data Path

AD9877

SIGMA-DELTA OUTPUTS

The AD9877 contains two independent sigma-delta outputs that provide a digital logic bit stream with an average duty cycle that varies between 0% and 4095/40.96%, depending on the programmed code, as shown in Figure 5.

Figure 5. Sigma-Delta Output Signals

These bitstreams can be low-pass filtered to generate programmable dc voltages of:

$$V_{DC} = (\text{Sigma} - \text{DeltaCode}/4096)(V_H) + V_L$$

where $V_H = V_{DRVDD} - 0.6$ V and $V_L = 0.4$ V.

Figure 6. Sigma-Delta RC Filter

In cable modem set-top box applications, the outputs can be used to control external variable gain amplifiers and RF tuners. A simple single-pole RC low-pass filter provides sufficient filtering (Figure 6).

In more demanding applications where additional gain, level shift, or drive capability is required, a first or second order active filter might be considered for each sigma-delta output (Figure 7).

Figure 7. Sigma-Delta Active Filter with Gain and Offset

SERIAL INTERFACE FOR REGISTER CONTROL

The AD9877 serial port is a flexible, synchronous serial communications port allowing easy interface to many industry-standard microcontrollers and microprocessors. The interface allows read/write access to all registers that configure the AD9877. Single or multiple byte transfers are supported. Also, the interface can be programmed to read words either MSB first or LSB first. The AD9877's serial interface port I/O can be configured to have one bidirectional I/O (SDIO) pin or two unidirectional I/O (SDIO/SDO) pins.

General Operation of the Serial Interface

There are two phases to a communication cycle with the AD9877. Phase 1 is the instruction cycle, which is the writing of an instruction byte into the AD9877, coincident with the first eight SCLK rising edges. The instruction byte provides the AD9877 serial port controller with information regarding the data transfer cycle, Phase 2 of the communication cycle. The Phase 1 instruction byte defines whether the upcoming data transfer is read or write, the number of bytes in the data transfer, and the starting register address for the first byte of the data transfer. The first eight SCLK rising edges of each communication cycle are used to write the instruction byte into the AD9877.

The eight remaining SCLK edges are for Phase 2 of the communication cycle. Phase 2 is the actual data transfer between the AD9877 and the system controller. Phase 2 of the communication cycle is a transfer of 1 to 4 data bytes as determined by the instruction byte. Registers change immediately upon writing to the last bit of each transfer byte.

Instruction Byte

The Instruction Byte contains the following information:

MSB				LSB			
17	16	15	14	13	12	11	10
R/W	N1	N0	A4	A3	A2	A1	A0

The R/W Bit of the Instruction Byte determines whether a read or a write data transfer will occur after the Instruction Byte write. Logic high indicates a read operation. Logic zero indicates a write operation. The N1:N0 Bits determine the number of bytes to be transferred during the data transfer cycle. The bit decodes are shown in the table below:

N1	N0	Description
0	0	Transfer 1 Byte
0	1	Transfer 2 Bytes
1	0	Transfer 3 Bytes
1	1	Transfer 4 Bytes

The Bits A4:A0 determine which register is accessed during the data transfer portion of the communications cycle. For multibyte transfers, this address is the starting byte address. The remaining register addresses are generated by the AD9877.

Serial Interface Port Pin Description

SCLK—Serial Clock. The serial clock pin is used to synchronize data transfers from the AD9877 and to run the serial port state machine. The maximum SCLK frequency is 15 MHz. Input data to the AD9877 is sampled on the rising edge of SCLK. Output data changes on the falling edge of SCLK.

\overline{CS} —Chip Select. Active low input starts and gates a communication cycle. It allows multiple devices to share a common serial port bus. The SDO and SDIO pins go to a high impedance state when \overline{CS} is high. Chip select should stay low during the entire communication cycle.

SDIO—Serial Data I/O. Data is always written into the AD9877 on this pin. However, this pin can be used as a bidirectional data line. The configuration of this pin is controlled by Bit 7 of Register 0. The default is logic 0, which configures the SDIO pin as unidirectional.

SDO—Serial Data Out. Data is read from this pin for protocols that use separate lines for transmitting and receiving data. In the case where the AD9877 operates in a single bidirectional I/O mode, this pin does not output data and is set to a high impedance state.

MSB/LSB Transfers

The AD9877 serial port can support both the most significant bit (MSB) first or the least significant bit (LSB) first data formats. This functionality is controlled by the LSB first bit in Register 0. The default is MSB first.

When this bit is set active high, the AD9877 serial port is in LSB first format. In LSB first mode, the instruction byte and data bytes must be written from the least significant bit to the most significant bit. In LSB first mode, the serial port internal byte address generator increments for each byte of the multibyte communication cycle.

When this bit is set default low, the AD9877 serial port is in MSB first format. In MSB first mode, the instruction byte and data bytes must be written from the most significant bit to the least significant bit. In MSB first mode, the serial port internal byte address generator decrements for each byte of the multibyte communication cycle.

When incrementing from 0x1F, the address generator changes to 0x00. When decrementing from 0x00, the address generator changes to 0x1F.

Notes on Serial Port Operation

The AD9877 serial port configuration bits reside in Bit 6 and Bit 7 of Register Address 00h. It is important to note that the configuration changes immediately upon writing to the last bit of the register. For multibyte transfers, writing to this register may occur during the middle of the communication cycle. Care must be taken to compensate for this new configuration for the remaining bytes of the current communication cycle.

The same considerations apply to setting the RESET Bit in Register Address 00h. All other registers are set to their default values, but the software reset does not affect the bits in Register Address 00h.

It is recommended to use only single byte transfers when changing serial port configurations or initiating a software reset.

A write to Bits 1, 2, and 3 of Address 00h with the same logic levels as Bits 7, 6, and 5 (bit pattern: XY1001YX binary) allows the host processor to reprogram a lost serial port configuration and to reset the registers to their default values. A second write to Address 00h with RESET Bit low and serial port configuration as specified above (XY) reprograms the OSCIN multiplier setting. A changed f_{SYSCLK} frequency is stable after a maximum of 200 f_{MCLK} cycles.

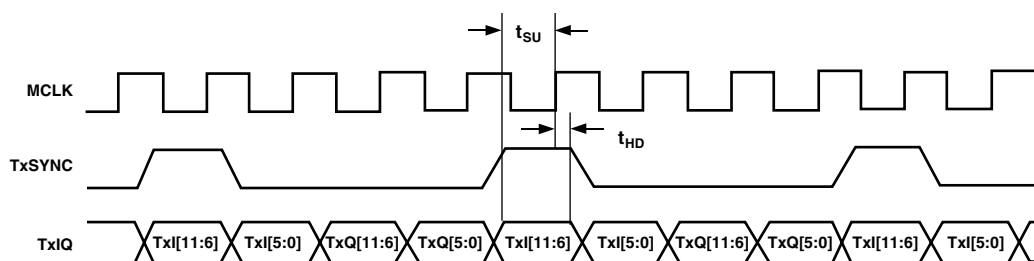

Figure 11. Transmit Timing Diagram

AD9877

TRANSMIT PATH (TX)

Transmit Timing

The AD9877 provides a master clock MCLK and expects 6-bit multiplexed TxIQ data on each rising edge. Transmit symbols are framed with the TxSYNC input. TxSYNC high indicates the start of a transmit symbol. Four consecutive 6-bit data packages form a symbol (I MSB, I LSB, Q MSB, and Q LSB).

Data Assembler

The input data stream is representative complex data. Two 6-bit words form a 12-bit symbol component (two's complement format). Four input samples are required to produce one I/Q data pair. The I/Q sample rate f_{IQCLK} at the input to the first half-band filter is a quarter of the input data rate f_{MCLK} .

The I/Q sample rate f_{IQCLK} puts a bandwidth limit on the maximum transmit spectrum. This is the familiar Nyquist limit and is equal to one-half f_{IQCLK} , which hereafter will be referred to as f_{NYQ} .

Half-Band Filters (HBFs)

HBF 1 and HBF 2 are both interpolating filters, each of which doubles the sampling rate. Together, HBF 1 and HBF 2 have 26 taps and provide a factor of 4 increase in the sampling rate ($4 \times f_{IQCLK}$ or $8 \times f_{NYQ}$).

In relation to phase response, both HBFs are linear phase filters. As such, virtually no phase distortion is introduced within the pass band of the filters. This is an important feature, since phase distortion is generally intolerable in a data transmission system.

Cascaded Integrator-COMB (CIC) Filter

A CIC filter is unlike a typical FIR filter in that it offers the flexibility to handle differing input and output sample rates in any integer ratios. In the AD9877, the CIC filter is configured as a programmable interpolator and provides a sample rate increase by a factor of $R = 3$ or $R = 4$. In addition to the ability to provide a change in the sample rate between the input and the output, a CIC filter also has an intrinsic low pass frequency response characteristic. The frequency response of a CIC filter is dependent on three factors:

1. The rate change ratio, R .
2. The order of the filter, n .
3. The number of unit delays per stage, m .

It can be shown that the system function $H(z)$ of a CIC filter is given by:

$$H(z) = \left(\left(\frac{1}{R} \right) \frac{1 - z^{-Rm}}{1 - z^{-1}} \right)^n = \left(\left(\frac{1}{R} \right) \sum_{k=0}^{Rm-1} z^{-k} \right)^n$$

The form on the far right has the advantage of providing a result for $z = 1$ (corresponding to zero frequency or dc). The alternate form yields an indeterminate form (0/0) for $z = 1$ but is otherwise identical. The only variable parameter for the AD9877's CIC filter is R ; m and n are fixed at 1 and 3, respectively. Thus, the CIC system function for the AD9877 simplifies to:

$$H(z) = \left(\left(\frac{1}{R} \right) \frac{1 - z^{-R}}{1 - z^{-1}} \right)^3 = \left(\left(\frac{1}{R} \right) \sum_{k=0}^{R-1} z^{-k} \right)^3$$

The transfer function is given by:

$$|H(f)| = \left(\left(\frac{1}{R} \right) \frac{1 - e^{-j(2\pi fR)}}{1 - e^{-j2\pi f}} \right)^3 = \left| \left(\left(\frac{1}{R} \right) \frac{\sin(\pi fR)}{\sin(\pi f)} \right) \right|^3$$

The frequency response in this form is such that f is scaled to the output sample rate of the CIC filter. That is, $f = 1$ corresponds to the frequency of the output sample rate of the CIC filter. $H(z)$ will yield the frequency response with respect to the input sample of the CIC filter.

Combined Filter Response

The combined frequency response of HBF 1, HBF 2, and CIC is shown in Figures 12a to 12c and Figures 13a to 13c.

The usable bandwidth of the filter chain puts a limit on the maximum data rate that can be propagated through the AD9877. A look at the pass band detail of the combined filter response (Figures 12d and 13d) indicates that in order to maintain an amplitude error of no more than 1 dB, we are restricted to signals having a bandwidth of no more than about 60% of f_{NYQ} . Thus, in order to keep the bandwidth of the data in the flat portion of the filter pass band, the user must oversample the baseband data by at least a factor of 2 prior to representing it to the AD9877. Note that without oversampling, the Nyquist bandwidth of the baseband data corresponds to the f_{NYQ} . As such, the upper end of the data bandwidth will suffer 6 dB or more of attenuation due to the frequency response of the digital filters.

Furthermore, if the baseband data applied to the AD9877 has been pulse shaped, there is an additional concern. Typically, pulse shaping is applied to the baseband data via a filter having a raised cosine response. In such cases, an α value is used to modify the bandwidth of the data where the value of α is such that $0 \leq \alpha \leq 1$. A value of 0 causes the data bandwidth to correspond to the Nyquist bandwidth. A value of 1 causes the data bandwidth to be extended to twice the Nyquist bandwidth. Thus, with $2 \times$ oversampling of the baseband data and $\alpha = 1$, the Nyquist bandwidth of the data will correspond with the I/Q Nyquist bandwidth. As stated earlier, this results in problems near the upper edge of the data bandwidth due to the frequency response of the filters. The maximum value of α that can be implemented is 0.45. This is because the data bandwidth becomes:

$$1/2 (1 + \alpha) f_{NYQ} = 0.725 f_{NYQ}$$

which puts the data bandwidth at the extreme edge of the flat portion of the filter response.

If a particular application requires an α value between 0.45 and 1, the user must oversample the baseband data by at least a factor of 4. The combined HB1, HB2, and CIC filter introduces, over the frequency range of the data to be transmitted, a worst-case droop of less than 0.2 dB.

Figure 14. 16-Quadrature Modulation

Tx Signal Level Considerations

The quadrature modulator itself introduces a maximum gain of 3 dB in the signal level. To visualize this, assume that both the I data and Q data are fixed at the maximum possible digital value, x . Then the output of the modulator, z , is:

$$z = [x \cos(\omega t) - x \sin(\omega t)]$$

It can be shown that $|z|$ assumes a maximum value of:

$$|z| = \sqrt{(x^2 + x^2)} = x\sqrt{2} \text{ (a gain of +3 dB)}$$

However, if the same number of bits were used to represent the $|z|$ values as is used to represent the x values, an overflow would occur. To prevent this possibility, an effective -3 dB attenuation is internally implemented on the I and Q data path.

$$(|z| = \sqrt{(1/2 + 1/2)} = x)$$

Figure 15. Signal Level Contribution

The following example assumes a Pk/rms level of 10 dB:

$$\text{Maximum Symbol Component Input Value} = \pm (2047 \text{ LSBs} - 0.2 \text{ dB}) = \pm 2000 \text{ LSBs}$$

$$\text{Maximum Complex Input rms Value} = 2000 \text{ LSBs} + 6 \text{ dB} - Pk/rms \text{ (dB)} = 1265 \text{ LSBs rms}$$

Maximum Complex Input rms Value calculation uses both I and Q symbol components, which adds a factor of 2 (= 6 dB) to the formula.

Table II shows typical IQ input test signals with amplitude levels related to 12-bit full scale (FS).

Tx Throughput and Latency

Data inputs effect the output fairly quickly but remain effective due to AD9877's filter characteristics. Data transmit latency through the AD9877 is easiest to describe in terms of f_{SYSCLK} clock cycles ($4 f_{MCLK}$). The numbers quoted are when an effect is first seen after an input value change.

Table II. IQ Input Test Signals

Analog Output	Digital Input	Input Level	Modulator Output Level
Single Tone ($f_c - f$)	I = $\cos(f)$ Q = $\cos(f + 90^\circ) = -\sin(f)$	FS - 0.2 dB FS - 0.2 dB	FS - 3.0 dB
Single Tone ($f_c + f$)	I = $\cos(f)$ Q = $\cos(f + 270^\circ) = +\sin(f)$	FS - 0.2 dB FS - 0.2 dB	FS - 3.0 dB
Dual Tone ($f_c \pm f$)	I = $\cos(f)$ Q = $\cos(f + 180^\circ) = -\cos(f)$ or Q = $+\cos(f)$	FS - 0.2 dB FS - 0.2 dB	FS

Latency of I/Q data entering the data assembler (AD9877 input) to the DAC output is $119 f_{\text{SYSCLK}}$ clock cycles ($29.75 f_{\text{MCLK}}$ cycles). DC values applied to the data assembler input will take up to $176 f_{\text{SYSCLK}}$ clock cycles ($44 f_{\text{MCLK}}$ cycles) to propagate and settle at the DAC output.

Frequency hopping is accomplished via changing the PROFILE input pins. The time required to switch from one frequency to another is less than $232 f_{\text{SYSCLK}}$ cycles ($58.5 f_{\text{MCLK}}$ cycles).

D/A Converter

A 12-bit digital-to-analog converter (DAC) is used to convert the digitally processed waveform into an analog signal. The worst-case spurious signals due to the DAC are the harmonics of the fundamental signal and their aliases (please see Analog Devices' DDS Tutorial at www.analog.com/dds). The conversion process will produce aliased components of the fundamental signal at $n \times f_{\text{SYSCLK}} \pm f_{\text{CARRIER}}$ ($n = 1, 2, \text{ and } 3$). These are typically filtered with an external RLC filter at the DAC output. It is important for this analog filter to have a sufficiently flat gain and linear phase response across the bandwidth of interest to avoid modulation impairments. A relatively inexpensive seventh order elliptical low-pass filter is sufficient to suppress the aliased components for HFC network applications.

The AD9877 provides true and complement current outputs. The full-scale output current is set by the R_{SET} resistor at Pin 49 and the DAC gain register. Assuming maximum DAC gain, the value of R_{SET} for a particular full-scale I_{OUT} is determined using the following equation:

$$R_{\text{SET}} = 32 V_{\text{DACRSET}} / I_{\text{OUT}} = 39.4 / I_{\text{OUT}}$$

For example, if a full-scale output current of 20 mA is desired, then $R_{\text{SET}} = (39.4/0.02) \Omega$ or approximately 2 k Ω .

The following equation calculates the full-scale output current, including the programmable DAC gain control.

$$I_{\text{OUT}} = \left[39.4 / R_{\text{SET}} \right] \times 10^A \left((-7.5 + 0.5 N_{\text{GAIN}}) / 20 \right)$$

Where N_{GAIN} is the value of DAC Fine Gain Control[3:0].

The full-scale output current range of the AD9877 is 4 to 20 mA. Full-scale output currents outside of this range will degrade SFDR performance. SFDR is also slightly affected by output matching, that is, the two outputs should be terminated equally for best SFDR performance. The output load should be located as close as possible to the AD9877 package to minimize stray capacitance and inductance. The load may be a simple resistor to ground, an op amp current-to-voltage converter, or a transformer-coupled circuit. It is best not to attempt to directly drive highly reactive loads (such as an LC filter). Driving an LC filter without a transformer requires that the filter be doubly terminated for best performance, that is, the filter input and output should both be resistively terminated with the appropriate values. The parallel combination of the two terminations will determine the load that the AD9877 will see for signals within the filter pass band.

For example, a 50 Ω terminated input/output low-pass filter will look like a 25 Ω load to the AD9877. The output compliance voltage of the AD9877 is -0.5 V to $+1.5 \text{ V}$. Any signal developed at the DAC output should not exceed 1.5 V, otherwise signal distortion will result. Furthermore, the signal may extend below ground as much as 0.5 V without damage or signal distortion. The AD9877 true and complement outputs can be differentially combined for common-mode rejection

using a broadband 1:1 transformer. Using a grounded center tap results in signals at the AD9877 DAC output pins that are symmetrical about ground. As previously mentioned, by differentially combining the two signals, the user can provide some degree of common-mode signal rejection. A differential combiner might consist of a transformer or an operational amplifier. The object is to combine or amplify only the difference between two signals and to reject any common, usually undesirable characteristic, such as 60 Hz hum or clock feedthrough that is equally present on both individual signals.

Connecting the AD9877 true and complement outputs to the differential inputs of the gain-programmable cable drivers AD8321/AD8323 or AD8322/AD8327 provides an optimized solution for the standard-compliant cable modem upstream channel. The cable driver's gain can be programmed through a direct 3-wire interface using the AD9877's profile registers.

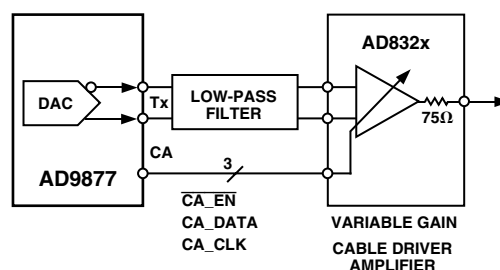

Figure 16. Cable Amplifier Connection

Figure 17. Cable Amplifier Interface Timing

PROGRAMMING THE AD8321/AD8325 OR AD8322/AD8327 CABLE DRIVER AMPLIFIER GAIN CONTROL

Programming the gain of the AD832x family cable driver amplifier can be accomplished via the AD9877 cable amplifier control interface. Four 8-bit registers within the AD9877 (one per profile) store the gain value to be written to the serial 3-wire port. Typically either AD8321/AD8325 or AD8322/AD8327 variable gain cable amplifiers are connected to the chip's 3-wire cable amplifier interface. The Tx Gain Control Select Bit in Register 0F changes the interpretation of the bits in Registers 13, 17, 1B, and 1F. (see Cable Driver Gain Control Register description).

Data transfers to the gain-programmable cable driver amplifier are initiated by four conditions. Each is described below:

1. Power-Up and Hardware Reset—Upon initial power-up and every hardware reset, the AD9877 clears the contents of the gain control registers to 0, which defines the lowest gain setting of the AD832x. Thus, the AD9877 writes all 0s out of the 3-wire cable amplifier control interface.
2. Software Reset—Writing a 1 to Bit 5 of Address 00 initiates a software reset. On a software reset, the AD9877 clears the contents of the gain control registers to 0 for the lowest gain and sets the profile select to 0. The AD9877 writes all 0s out of the 3-wire cable amplifier control interface if the gain was on a different setting (different from 0) before.

AD9877

3. Change in Profile Selection—The AD9877 samples the PROFILE[1] and PROFILE[2] input pins together with the two profile select bits and writes to the AD832x gain control registers if a change in profile and gain is determined. The data written to the cable driver amplifier comes from the AD9877 gain control register associated with the current profile.
4. Write to AD9877 Cable Driver Amplifier Control Registers—The AD9877 will write gain control data associated with the current profile to the AD832x whenever the selected AD9877 cable driver amplifier gain setting is changed.

Once a new stable gain value has been detected (48 MCLK to 64 MCLK cycles after initiation) data write starts with CA_CS going low. The AD9877 will always finish a write sequence to the cable driver amplifier once it is started. The logic controlling data transfers to the cable driver amplifier uses up to 200 MCLK cycles and has been designed to prevent erroneous write cycles from ever occurring.

RECEIVE PATH (Rx)

ADC Theory of Operation

The AD9877's analog-to-digital converters implement pipelined multistage architectures to achieve high sample rates while consuming low power. Each ADC distributes the conversion over several smaller ADC subblocks, refining the conversion with progressively higher accuracy as it passes the results from stage to stage. As a consequence of the distributed conversion, ADCs require a small fraction of the 2^n comparators used in a traditional n-bit flash-type ADC. A sample-and-hold function within each of the stages permits the first stage to operate on a new input sample while the remaining stages operate on preceding samples. Each stage of the pipeline, excluding the last, consists of a low resolution flash ADC connected to a switched capacitor DAC and interstage residue amplifier (MDAC). The residue amplifier amplifies the difference between the reconstructed DAC output and the flash input for the next stage in the pipeline. One bit of redundancy is used in each one of the stages to facilitate digital correction of flash errors. The last stage simply consists of a flash ADC.

Figure 18. ADC Architecture

The analog inputs of the AD9877 incorporate a novel structure that merges the input sample-and-hold amplifiers (SHA) and the first pipeline residue amplifiers into single, compact switched capacitor circuits. This structure achieves considerable noise and power savings over a conventional implementation that uses separate amplifiers by eliminating one amplifier in the pipeline. By matching the sampling network of the input SHA with the first stage flash ADC, the ADCs can sample inputs well beyond the Nyquist frequency with no degradation in performance.

The digital data outputs of the ADCs are represented in straight binary format. They saturate to full scale or zero when the input signal exceeds the input voltage range.

Receive Timing

The AD9877 sends multiplexed data to the RxIQ outputs on every rising edge of MCLK. The data stream consists of two nibbles of I data followed by two nibbles of Q data. The RxSYNC pulse frames the I/Q data and is high coincidentally with the most significant nibble of the I data-word. If the 8-bit I/Q ADC is in power-down mode, the RxSYNC signal will not be generated.

The 12-bit ADC data is sent to the IF[11:0] outputs on every second falling edge of MCLK.

In its default setting, the OSCOUT pin provides a buffered version of f_{OSCIN} . OSCOUT can be used as a qualifying clock for the Rx data when the ratio between OSCIN multiplier and OSCIN divider is programmed to be 2 ($M/N = 2$) or when the ADC sampling is selected to be derived from f_{OSCIN} directly.

Driving the Analog Inputs

Figure 19 illustrates the equivalent analog inputs of the AD9877 (a switched capacitor input). Bringing CLK to a logic high opens Switch S3 and closes Switches S1 and S2. The input source is connected to AIN and must charge capacitor C_H during this time. Bringing CLK to a logic low opens S2, and then Switch S1 opens followed by closing S3. This puts the input in the hold mode.

Figure 19. Differential Input Architecture

The structure of the input SHA places certain requirements on the input drive source. The combination of the pin capacitance and the hold capacitance, C_H , is typically less than 5 pF. The input source must be able to charge or discharge this capacitance to its n-bit accuracy in one-half of a clock cycle. When the SHA goes into track mode, the input source must charge or discharge capacitor C_H from the voltage already stored on C_H to the new voltage. In the worst case, a full-scale voltage step on the input source must provide the charging current through the R_{ON} (100 Ω) of Switch S1 and quickly (within 1/2 CLK period) settle. This situation corresponds to driving a low input impedance. On the other hand, when the source voltage equals the value previously stored on C_H , the hold capacitor requires no input current and the equivalent input impedance is extremely high. Adding series resistance between the output of the signal source and the AIN pin reduces the drive requirements placed on the signal source. Figure 20 shows this configuration.

Figure 20. Simple ADC Drive Configuration

The bandwidth of the particular application limits the size of this resistor. To maintain the performance outlined in the data sheet specifications, the resistor should be limited to $50\ \Omega$ or less. For applications with signal bandwidths less than 10 MHz, the user may proportionally increase the size of the series resistor. Alternatively, adding a shunt capacitance between the AIN pins can lower the ac load impedance. The value of this capacitance will depend on the source resistance and the required signal bandwidth. In systems that must use dc-coupling, use an op amp to comply with the input requirements of the AD9877.

Op Amp Selection Guide

Op amp selection for the AD9877 is highly application dependent. In general, the performance requirements of any given application can be characterized by either time domain or frequency domain constraints. In either case, one should carefully select an op amp that preserves the performance of the ADC. This task becomes challenging when one considers the AD9877's high performance capabilities coupled with other system level requirements, such as power consumption and cost. The ability to select the optimal op amp may be further complicated by either limited power supply availability and/or limited acceptable supplies for a desired op amp.

Newer, high performance op amps typically have input and output range limitations in accordance with their lower supply voltages. As a result, some op amps will be more appropriate in systems where ac-coupling is allowed. When dc-coupling is required, op amp headroom constraints (such as rail-to-rail op amps), or ones where larger supplies can be used, should be considered. Analog Devices offers differential output operational amplifiers, such as the AD8131, with a fixed gain of 2. It can be used for differential or single-ended-to-differential signal conditioning with 8-bit performance to directly drive ADC inputs. The AD8138 is a higher performance version of the AD8131. It provides 12-bit performance and allows different gain settings. Please contact the factory or local sales office for updates on Analog Devices' latest amplifier product offerings.

ADC Differential Inputs

The AD9877 uses a 1 V p-p input span for the 8-bit ADC inputs and a 2 V p-p for the 12-bit ADC. Since not all applications have a signal preconditioned for differential operation, there is often a need to perform a single-ended-to-differential conversion. In systems that do not need a dc input, an RF transformer with a center tap is the best method to generate differential inputs beyond 20 MHz for the AD9877. This provides all the benefits of operating the ADC in the differential mode without contributing additional noise or distortion. An RF transformer also has the added benefit of providing electrical isolation between the signal source and the ADC.

An improvement in THD and SFDR performance can be realized by operating the AD9877 in differential mode. The performance enhancement between the differential and single-ended mode is most considerable as the input frequency approaches and goes beyond the Nyquist frequency (i.e., $f_{IN} > f_s/2$).

The AD8131 provides a convenient method of converting a single-ended signal to a differential signal. This is an ideal method for generating a direct coupled signal to the AD9877.

The AD8131 will accept a signal swinging below 0 V and shift it to an externally provided common-mode voltage. The AD8131 configuration is shown in Figure 21.

Figure 21. Single-Ended-to-Differential Input Drive

Figure 22 shows the schematic of a possible transformer coupled circuit. Transformers with turn ratios (n_2/n_1) other than 1 may be selected to optimize the performance of a given application. For example, selecting a transformer with a higher impedance ratio (e.g., minicircuits T16-6T with an impedance ratio of $(z_2/z_1) = 16 = (n_2/n_1)^2$) effectively "steps up" the signal amplitude, thus further reducing the output voltage swing of the signal source. In Figure 22, a resistor $R1$ is added between the analog inputs to match the source impedance R as in the formula:

$$R = [R1 \parallel R_{AIN}] (Z_1/Z_2)$$

Figure 22. Transformer Coupled Input

ADC Voltage References

The AD9877 has two independent internal references for its 8-bit and 12-bit ADCs. Both 8-bit ADCs have a 1 V p-p input and share one internal reference source. The 12-bit ADC, however, is designed for 2 V p-p input voltages and provides its own internal reference. Figure 2 shows the proper connections of the reference pins REFT and REFB.

External references may be necessary for systems that require high accuracy gain matching between ADCs or improvements in temperature drift and noise characteristics. External references REFT and REFB need to be centered at $AVDD/2$ with offset voltages as specified:

$$\begin{aligned} \text{REFT8: } & AVDDIQ/2 + 0.25\ \text{V}, \text{ REFB8: } AVDDIQ/2 - 0.25\ \text{V} \\ \text{REFT12: } & AVDD/2 + 0.5\ \text{V}, \text{ REFB12: } AVDD/2 - 0.5\ \text{V} \end{aligned}$$

AD9877

A differential level of 0.5 V between the reference pins results in a 1 V p-p ADC input level AIN. A differential level of 1 V between the reference pins results in a 2 V p-p ADC input level AIN. Internal reference sources can be powered down when external references are used (Register Address 02).

PCB DESIGN CONSIDERATIONS

Although the AD9877 is a mixed-signal device, the part should be treated as an analog component. The digital circuitry on-chip has been specially designed to minimize the impact that the digital switching noise will have on the operation of the analog circuits. Following the power, grounding, and layout recommendations in this section will help you get the best performance from the MxFE.

Component Placement

If the three following guidelines of component placement are followed, chances for getting the best performance from the MxFE are greatly increased. First, manage the path of return currents flowing in the ground plane so that high frequency switching currents from the digital circuits do not flow on the ground plane under the MxFE or analog circuits. Second, keep noisy digital signal paths and sensitive receive signal paths as short as possible. Third, keep digital (noise generating) and analog (noise susceptible) circuits as far away from each other as possible.

In order to best manage the return currents, pure digital circuits that generate high switching currents should be closest to the power supply entry. This will keep the highest frequency return current paths short and prevent them from traveling over the sensitive MxFE and analog portions of the ground plane. Also, these circuits should be generously bypassed at each device, which will further reduce the high frequency ground currents. The MxFE should be placed adjacent to the digital circuits, such that the ground return currents from the digital sections will not flow in the ground plane under the MxFE. The analog circuits should be placed furthest from the power supply.

The AD9877 has several pins that are used to decouple sensitive internal nodes. These pins are REFIO, REFB8, REFT8, REFB12, and REFT12. The decoupling capacitors connected to these points should have low ESR and ESL. These capacitors should be placed as close to the MxFE as possible and be connected directly to the analog ground plane.

The resistor connected to the FSADJ pin and the RC network connected to the PLLFILT pin should also be placed close to the device and connected directly to the analog ground plane.

Power Planes and Decoupling

The AD9877 evaluation board demonstrates a good power supply distribution and decoupling strategy. The board has four layers: two signal layers, one ground plane, and one power plane. The power plane is split into a 3 VDD section used for the 3 V analog supply pins of the AD9877 and a VANLG section that supplies the higher voltage analog components on the board. That 3 VDD section will typically have the highest frequency

currents on the power plane and should be kept the furthest from the MxFE and analog sections of the board. The DVDD portion of the plane brings the current used to power the digital portion of the MxFE to the device. This should be treated similarly to the 3 VDD power plane and be kept from going underneath the MxFE or analog components. The MxFE should largely sit above the AVDD portion of the power plane.

The AVDD and DVDD power planes may be fed from the same low noise voltage source; however, they should be decoupled from each other to prevent the noise generated in the DVDD portion of the MxFE from corrupting the AVDD supply. This can be done by using ferrite beads between the voltage source and DVDD and between the source and AVDD. Both DVDD and AVDD should have a low ESR, bulk decoupling capacitor on the MxFE side of the ferrite as well as low ESR, ESL decoupling capacitors on each supply pin (i.e., the AD9877 requires 17 power supply decoupling caps). The decoupling caps should be placed as close to the MxFE supply pins as possible. An example of the proper decoupling is shown in the AD9877 evaluation board schematic.

Ground Planes

In general, if the component placing guidelines discussed earlier can be implemented, it is best to have at least one continuous ground plane for the entire board. All ground connections should be made as short as possible. This will result in the lowest impedance return paths and the quietest ground connections.

If the components cannot be placed in a manner which would keep the high frequency ground currents from traversing under the MxFE and analog components, it may be necessary to put current-steering channels into the ground plane to route the high frequency currents around these sensitive areas. These current-steering channels should be made only when and where necessary.

Signal Routing

The digital Rx and Tx signal paths should be kept as short as possible. Also, the impedance of these traces should have a controlled impedance of about 50 Ω . This will prevent poor signal integrity and the high currents that can occur during undershoot or overshoot caused by ringing. If the signal traces cannot be kept shorter than about 1.5 in., then series termination resistors (33 Ω to 47 Ω) should be placed close to all signal sources. It is a good idea to series terminate all clock signals at their source regardless of trace length.

The receive (I IN, Q IN, and RF IN) signals are the most sensitive signals on the entire board. Careful routing of these signals is essential for good receive path performance. The Rx \pm signals form a differential pair and should be routed together as a pair. By keeping the traces adjacent to each other, noise coupled onto the signals will appear as common mode and will be largely rejected by the MxFE receive input. Keeping the driving point impedance of the receive signal low and placing any low-pass filtering of the signals close to the MxFE will further reduce the possibility of noise corrupting these signals.
